With respect to *mothers*, a pair of contrasting gender-related ERCS Time × Attachment simple interaction effects emerged for mothers' ERCS positive interaction and hostile treatment scores, but not for mothers' ERCS negative interaction scores, $F(3, 700) = 2.08$, $p = .10$. With respect to mothers' ERCS positive interaction scores, a significant ERCS Time × Attachment simple interaction effect emerged for mothers of *boys* only, $F(3, 698) = 2.75$, $p < .05$: Whereas mothers of secure boys' memory for the positive features of the conflict remained stable during the 6-week period, $M_{\text{T1–T2}} = -0.05$, $SE = 0.10$, $t_{\text{T1–T2}}(627) = -0.49$, $p = .63$, $g = .02$, mothers of insecure boys showed a decrease in their propensity to remember the conflict as positive, $M_{\text{T1–T2}} = 0.37$, $SE = 0.13$, $t_{\text{T1–T2}}(620) = 2.82$, $p < .01$, $g = .11$ (see Figure 4). Inspection of the difference scores between mothers of secure boys' T1 and T2 ERCS positive interaction scores and their positive adolescent–mother dyadic conflict behavior scores indicated that secure boys' mothers' perceptions of

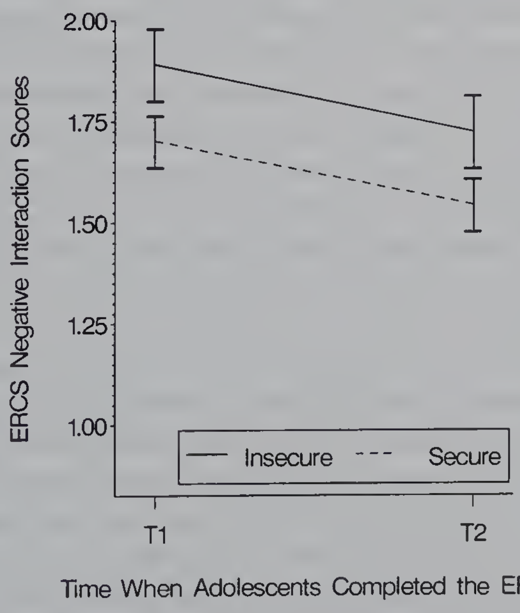

Figure 3. Adult Attachment Interview–related changes in adolescents' Emotional Response to Conflict Scale negative interaction scores for their conflict discussions with father.

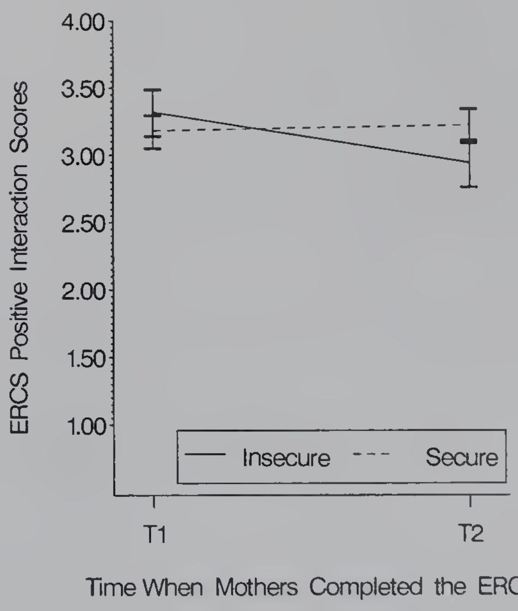

Figure 4. Adult Attachment Interview–related changes in mothers' Emotional Response to Conflict Scale positive interaction scores for their conflict discussions with sons.

the positive features of the conflict did not differ significantly from the behavioral ratings at T1, $M_{\text{DiffT1}} = -0.22$, $SE = 0.16$, $t(494) = -1.33$, $p = .18$, $g = .06$, or T2, $M_{\text{DiffT2}} = -0.15$, $SE = 0.17$, $t(479) = -0.86$, $p = .39$, $g = .04$, and did not change over time in reference to the behavioral ratings, $M_{\text{DiffT1–DffT2}} = -0.07$, $SE = 0.12$, $t_{\text{T1–T2}}(611) = -0.57$, $p = .57$, $g = .02$. Insecure boys' mothers' perceptions of the positive features of the conflict also did not differ significantly from observed behavioral ratings at T1, $M_{\text{DiffT1}} = 0.12$, $SE = 0.23$, $t(494) = 0.51$, $p = .61$, $g = .02$, or T2, $M_{\text{DiffT2}} = -0.33$, $SE = 0.24$, $t(464) = -1.35$, $p = .18$, $g = .06$, but the change in insecure boys' mothers perceptions of the conflict—from more to less positive—over the 6-week period was significant compared with the behavioral ratings, $M_{\text{DiffT1–DffT2}} = 0.44$, $SE = 0.16$, $t_{\text{T1–T2}}(606) = 2.79$, $p < .01$, $g = .11$.

In contrast, with respect to mothers' ERCS hostile treatment scores, a significant ERCS Time × Attachment simple interaction effect emerged for mothers of *girls* only, $F(3, 698) = 2.75$, $p < .05$: Mothers of secure girls showed a decrease in their propensity to remember being treated with hostility by their daughters during the conflict, $M_{\text{T1–T2}} = 0.15$, $SE = 0.06$, $t_{\text{T1–T2}}(645) = 2.36$, $p < .05$, $g = .10$, whereas mothers of insecure girls' memory for being treated with hostility during the conflict remained stable during the 6-week period, $M_{\text{T1–T2}} = -0.02$, $SE = 0.09$, $t_{\text{T1–T2}}(639) = -0.22$, $p = .83$, $g = .01$ (see Figure 5). Inspection of the difference scores between mothers of secure girls' T1 and T2 ERCS hostile treatment scores and their daughters' hostile behavioral scores indicated that although these mothers' perceptions of being treated with hostility did not differ from the observed behavioral ratings of daughter hostility at T1, $M_{\text{DiffT1}} = 0.11$, $SE = 0.12$, $t(767) = 0.87$, $p = .38$, $g = .03$, or T2, $M_{\text{DiffT2}} = -0.14$, $SE = 0.13$, $t(740) = -1.09$, $p = .27$, $g = .04$, the change from perceiving receiving more hostility to less hostility compared with our observations over time was significant, $M_{\text{DiffT1–DffT2}} = 0.25$, $SE = 0.11$, $t_{\text{T2–T1}}(623) = 2.32$, $p < .05$, $g = .09$. Insecure girls' mothers' perceptions of being treated with hostility by their daughters did not differ from the behavioral ratings at T1, $M_{\text{DiffT1}} = 0.30$, $SE = 0.18$, $t(781) = 1.67$, $p = .10$, $g = .06$, or T2, $M_{\text{DiffT2}} = 0.34$, $SE = 0.18$, $t(709) = 1.84$, $p = .07$, $g = .07$, and did not change over time in reference to the behavioral ratings, $M_{\text{DiffT1–DffT2}} = -0.04$, $SE = 0.15$, $t_{\text{T1–T2}}(619) = -0.27$, $p = .79$, $g = .01$.

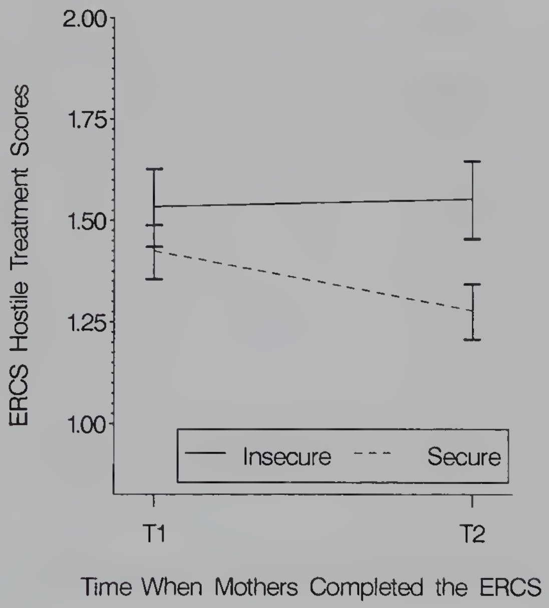

Figure 5. Adult Attachment Interview–related changes in mothers' Emotional Response to Conflict Scale hostile treatment scores for their conflict discussions with daughters.

For *fathers*, contrary to expectations, no significant ERCS Time × Attachment simple interaction effects or accompanying significant post hoc analyses examining T1–T2 differences emerged for adolescents' ERCS positive interaction, negative interaction, or hostile treatment scores (all post hoc *p*s ranged from .06 to .58).

Discussion

Given the importance of adolescent–parent conflict and evidence that memory for interpersonal experiences can lack accuracy over time (Baldwin, 1995; Fiske & Taylor, 1991), we examined attachment-related differences in the "reconstructions" of memory for adolescent–parent conflict and the ways in which these memory reconstructions were related to observer reports of the interactions. We found evidence that adolescents and their mothers, but not their fathers, reconstruct their perceptions of adolescent–parent conflict over time as a function of adolescent attachment, and we identified ways in which these reconstructions do and do not mesh with coder-rated observations of the conflict interaction.

First, findings suggest that when the memory for a specific adolescent–parent conflict degrades over a 6-week period, adolescents reconstruct their memories for the event as a function of their attachment organization. Thus, insecure adolescents, compared with secure adolescents, may have reported less favorable interactions over time because they were drawing on an insecure state of mind with respect to attachment to piece together the nature of these interactions. Overall, these attachment-related reconstructive memory biases fit well with and extend those that Feeney and Cassidy (2003) reported. However, unlike Feeney and Cassidy, we did not find links between our measure of attachment representations (the AAI) and every aspect of reconstructive memory for conflict with both mothers and fathers (i.e., positive interaction, negative interaction, and hostile treatment). Feeney and Cassidy, however, reported on links of adolescents' representations of a specific parent with memory about an interaction with that specific parent. We, on other hand, present findings indicating that a generalized, internal attachment organization (that is thought to be a consolidation of representations of mother, father, and other attachment figures; see Allen, 2008) relates to certain aspects of adolescents' memory for conflict with mother or father.

Moreover, in cases for which we found attachment-related memory biases, our analyses of difference scores between observer ratings and participant ratings of the interaction showed that secure adolescents had an initial bias to perceive their interactions with both mothers and fathers as *less* negative than observed scores, and this bias only grew stronger over time. These findings are particularly interesting because they suggest that secure adolescents are either not perceiving or not encoding the amount of negative content in their interactions with parents that observers perceive, and over time, this reporting bias is intensified because of their reliance on secure internal working models to aid memory recall. Insecure adolescents, on the other hand, showed a different pattern in their reports compared with observed scores of conflict. Insecure adolescents' initial ratings, like those of secure adolescents, were less negative than observer ratings, but there was no significant change over time in their ratings. Thus, although insecure adolescents perceived (or encoded) less negativity than did observers initially, they appeared to lack the protective memory bias that secure adolescents had that would allow them over time to recall the interaction as less negative. These findings illustrate the importance of considering comparisons between observers' assessments of behavior and self-reports over time to characterize the nature of attachment-based memory differences between secure and insecure adolescents.

It is interesting to note that although, as expected, relative to one another secure and insecure adolescents showed significantly distinct patterns of reconstructive memory, post hoc tests revealed findings that were not always expected. For instance, as expected, secure adolescents recalled their interactions with their mothers as less negative over time, yet contrary to expectation, insecure adolescents showed no significant change (rather than remembering their conflict interactions with their mothers as *more* negative over time). Research has shown that individuals tend to forget affect associated with unpleasant events more quickly than affect associated with pleasant events (Walker, Skowronski, & Thompson, 2003), and to minimize the affective experience of negative events (Taylor, 1991). The present results suggest that perhaps rather than having an overtly negative memory bias with respect to conflict interactions with mothers, insecure adolescents simply lack the normal protective memory process that secure adolescents use. (A similar lack of protective forgetting of negative affect emerged for insecure individuals in a study of counseling clients' memory for naturally occurring, in-session negative emotion: Specifically, clients high in attachment anxiety showed lower reductions in negative affect over the course of 1 week than did clients low in attachment anxiety; Woodhouse & Gelso, 2008.) In contrast to their interactions with their mothers, insecure adolescents *did* demonstrate a significant negative memory bias for interactions with their fathers, recalling the interaction as less positive than they had reported initially 6 weeks earlier. Secure adolescents, on the other hand, showed no significant change over time in their ratings of interaction with fathers. Moreover, the finding that secure versus insecure differences in adolescent reconstructive memory processes emerged in relation to negative emotion for mothers and positive emotion for fathers may indicate that reconstructive memory involves the salient emotional characteristics of these relationships (i.e., negativity is more frequent in adolescent–mother dyads, and positivity is more frequent in adolescent–father dyads; see Larson & Richards, 1994; Montemayor & Hanson, 1985; Smith & Forehand, 1986).

From an attachment perspective, attachment-related differences in reconstructive memory likely emerge because attachment organization serves as a structure through which new attachment-related information is processed rapidly and efficiently. These differences also likely stem from the proclivity of an individual's attachment organization to remain stable in the face of new information, especially information that would be inconsistent with previously obtained attachment-related knowledge (Bowlby, 1973). These notions are consistent with other theories in the social cognition literature, which state that internalized cognitive structures function to process social information in the most rapid and efficient ways possible, and in ways that are congruent with preexisting knowledge structures (Baldwin, 1992; Fiske & Taylor, 1991).

An additional important finding to emerge from this study was that adolescent AAI attachment security was linked not only to *adolescents'* reconstructive memory but also to *mothers'* reconstructive memory for conflict, such that compared with mothers of secure adolescents, mothers of insecure adolescents reconstructed aspects of the conflict interaction less favorably. Moreover, our follow-up analyses of how mothers of secure and insecure adolescents remembered their conflict interactions revealed expected patterns: Compared with mothers of secure boys, mothers of insecure boys typically remembered conflict interactions more negatively over time. Specifically, mothers of insecure boys initially rated the interaction no differently from the behavioral raters at T1 and T2; nevertheless, their memory for the positive aspects of the interaction became significantly less positive over time. Mothers of secure boys, on the other hand, likewise rated the positive aspects of the interaction no differently from the behavioral raters both at T1 and T2, yet did not show the significant decrease in their ratings of positivity that the mothers of insecure boys showed.

For mothers of girls, a somewhat different yet converging picture emerged. Mothers of secure girls reported less hostility over time as compared with mothers of insecure girls. Although neither T1 nor T2 ratings of daughters' hostility made by mothers of secure girls differed significantly from observer ratings of daughter hostility, there was a significant reduction in perceptions of hostility for mothers of secure girls. Mothers of insecure girls, on the other hand, likewise rated the hostile aspects of the interaction no differently from the behavioral raters both at T1 and T2, yet did not show the significant decrease in their ratings of hostility that the mothers of secure girls showed. Thus, mothers of insecure girls appeared to lack a protective ''forgetting'' of their daughters' hostility that mothers of secure girls seemed to demonstrate (although it is important to note that despite exhibiting an apparent protective ''forgetting,'' mothers of secure girls did not ultimately remember significantly less hostility than rated by observers).

These findings of maternal memory biases are noteworthy because they support attachment theorists' claims that parents' information-processing patterns are linked to their children's attachment security (see George & Solomon, 2008). It is striking that not only did we find compelling evidence with adolescents that is consistent with the idea that one's own state of mind with respect to attachment may guide one's memory (as predicted by attachment theory; Bowlby, 1969/1982; Main et al., 1985), we also found notable evidence of a link between one person's state of mind with respect to attachment and the social information processing of *another* person. If a mother has a memory bias that leads her to remember interactions less favorably over time, it is likely that she may feel differently about her adolescent child than she otherwise would. The adolescent's experience of having a mother who typically remembers interactions as more negative over time and feels more negatively about the adolescent may be a painful one. Moreover, such a negative maternal memory bias may lead the mother to feel, think, and act in ways that would interfere with the adolescent's tendency to view her as a secure base. Such a reduction in secure base experiences could contribute to the adolescent's overall insecure state of mind with respect to attachment. On the other hand, because the present study does not allow us to be certain about the direction of effects, it is important to consider that insecure adolescents might behave in ways that would make the mother less likely to remember positive aspects of the interaction. Regardless of the direction of the effect, it is notable that only mothers, and not fathers, showed a memory bias as a function of adolescent AAI. This finding is consistent with previous research suggesting that mothers may be more emotionally linked with their children than fathers (Larson & Richards, 1994; Montemayor, 1983; Youniss & Smollar, 1985). Further research will be necessary to better understand differences in the links between mother and father social information processing and adolescent attachment. Additionally, replication studies are needed to more fully understand the adolescent gender differences that emerged. For instance, mothers of secure adolescents reconstructed perceptions of girls' hostility as a function of girls' attachment but did not do the same with regard to boys' hostility. In most previous attachment research, gender has not moderated attachment-related findings (see Cassidy & Shaver, 2008, for reviews). It may be that hostility is more salient in mother–daughter relationships than in mother–son relationships, given empirical evidence that girls tend to engage in both greater conflict (as well as greater intimacy) with parents, particularly mothers, than do boys (Larson & Richards, 1994; Montemayor, 1983).

Although this study provides new insights into attachment-related memory processes, the reported findings should be considered within the context of the study's limitations. One limitation of the present study is that we were unable to examine links between parents' AAI classifications and reconstructive memory, an examination that might provide clues into possible pathways by which security of attachment can be transmitted within families across generations (see van IJzendoorn, 1995). It may be, for instance, that parental information processing mediates a (hypothesized) link between parent and adolescent attachment, such that once parent attachment is considered as a predictor of parental memory, the link between adolescent attachment and parental memory would be weakened (or no longer emerge). In other words, it may be that differences in mothers' attachment representations are driving differences in mothers' memory, mothers' behavior with the adolescent, and adolescent attachment.

Another limitation is that all families were maritally intact, limiting generalizability. Nevertheless, an important goal of the study was to examine memory biases for interactions occurring within relationships that adolescents have with both parents (see Collins & Russell, 1991, for a discussion of the importance of understanding the different contributions of mothers and fathers to development). Relatedly, our sample was nonclinical, relatively low risk, and relatively homogeneous with respect to socioeconomic status; memory processes may work differently in different kinds of samples. It is also important to note that our findings might have differed had we examined reconstructive memory over a different time span (e.g., over 6 months rather than 6 weeks); furthermore, we cannot rule out the possibility that the quality of adolescent–parent interactions after the laboratory visit contributed to how participants remembered the laboratory conflicts. An additional limitation is that we examined only secure versus insecure AAI group differences; future research (with samples containing larger numbers of insecure adolescents) is needed to reveal how adolescents with different AAI insecure classifications reconstruct memories for conflicts with parents. Finally, our results are correlational and do not allow us to determine causal relations. Although our interpretation of the data is consistent with attachment theory, the links that emerged in this investigation may have emerged for other reasons (e.g., insecurity may be associated with negative mood, and a wealth of data indicates that negative mood is linked to memory biases; see Haaga, Dyck, & Ernst, 1991).

In addition to addressing these limitations, future researchers could also examine reconstructive memory processes outside the context of adolescent–parent conflict (e.g., in contexts involving secure base support and safe haven provision), in other periods of development (e.g., childhood), and in relation to underlying psychophysiological processes (e.g., secure and insecure adolescents may employ different prefrontal emotion regulatory strategies when recalling past conflicts with parents). From a clinical perspective, these findings could have important implications for how adolescent–parent conflict is addressed during treatment. Instead of focusing solely on what occurs during an adolescent–parent conflict, clinicians might focus on how conflict is remembered over time as a function of adolescents' attachment security. By focusing on the attachment-related aftereffects of conflict, clinicians may be more resourceful in helping high-conflict adolescent–parent dyads overcome their difficulties.

Research examining the longer term influences of child care on children's development has expanded in recent years, but few studies have considered low-income children's experiences in community care arrangements. Using data from the Three-City Study ($N = 349$), the present investigation examines the influences of child care quality, extent and type on low-income children's development of behavior problems during middle childhood (7–11 years old). Higher levels of child care quality were linked to moderate reductions in externalizing behavior problems. High-quality child care was especially protective against the development of behavior problems for boys and African American children. Child care type and the extent of care that children experienced were generally unrelated to behavior problems in middle childhood.

Nonparental child care arrangements have become important contexts for early child development in the United States, with recent national estimates showing that approximately 12.2 million children under age 6 attend child care or preschool programs (Mulligan, Brimhall, & West, 2005). Economically disadvantaged children are slightly less likely than their advantaged counterparts to experience nonparental care during their preschool years, with 65% of children from poor families and 75% of children from nonpoor families regularly cared for in child care settings (Mulligan et al., 2005). Yet child care experiences may be particularly salient for low-income children's health and development. Faced with limited resources in their home environments, low-income children may be especially responsive either to the added supports of stimulating and responsive nonparental care or to the added risks of poor quality or extensive child care (Dearing, McCartney, & Taylor, 2009; Loeb, Bridges, Bassok, Fuller, & Rumberger, 2007; Magnuson, Ruhm, & Waldfogel, 2007).

Beyond a few model early intervention programs and a handful of short-term longitudinal studies, our knowledge is limited concerning the implications of child care experiences for low-income children's later development. Whether child care experiences have long-term effects on low-income children's socioemotional functioning, such as their

skills in regulating their emotions and behaviors, getting along with peers, and refraining from inappropriate behaviors, is understudied. Behavioral and emotional skills are essential for early school success and also have long-term implications for children's mental health and behavioral functioning (Raver, 2002). As children transition into formal schooling and traverse middle childhood, lower problem behaviors and better behavioral skills are central indicators of developmental success with long-term repercussions for healthy functioning (Huston & Ripke, 2006). Indeed, problem behaviors and behavioral and emotional skills that are established in middle childhood exhibit significant continuity across adolescence and even into adulthood (Huston & Ripke, 2006).

Grounded in bioecological models of development (Bronfenbrenner & Morris, 1998; Sameroff, 1994), this study seeks to enhance our understanding of how experiences in early education and care settings shape the development of behavior problems among economically disadvantaged children into middle childhood. Bioecological theory describes human development as the result of proximal processes and reciprocal interactions between individuals and their environments. Driving future development are proximal processes that occur in microsystems, along with the characteristics of individuals that affect the contexts that they select into as well as the experiences that they elicit in these contexts. Within the child care microsystem, this model argues that caregiving experiences as well as children's individual characteristics together influence future developmental trajectories, with potentially divergent influences for children with different characteristics (Bronfenbrenner & Ceci, 1994; Bronfenbrenner & Morris, 1998).

Effects of Child Care Quality on Children's Behavior Problems and Socioemotional Functioning

Research to date has identified three aspects of child care experiences that are important potential influences on children's well-being: quality of care, extent of care, and type of care setting. High-quality child care is characterized by caregivers who are warm and responsive, who provide materials and experiences that stimulate learning and emotional support, and who afford consistency and structure. Experiences in high-quality care settings promote socioemotional development by helping children learn to regulate their emotions, behaviors, and attention; to get along with peers; and to comply with rules and requests. Indeed, research has proliferated documenting the associations between early education and care experiences and children's socioemotional development. In concurrent and short-term longitudinal studies with large, socioeconomically diverse samples, high-quality child care has been found to predict modestly lower behavior problems and negative affect as well as enhanced peer relations, sociability, and compliance (e.g., Love et al., 2003; National Institute of Child Health and Human Development [NICHD] Early Child Care Research Network [ECCRN], 1998, 2001). If children show improved regulation, affect, and peer skills in early childhood in relation to child care experiences, it is hypothesized that these skills will carry forward, promoting an easier transition into formal schooling and in turn leading to better social functioning later in childhood (National Research Council and Institute of Medicine, 2000). There is little existing evidence, however, that links between child care quality and early socioemotional functioning endure into middle childhood. Findings from the NICHD ECCRN (2005) and Belsky et al. (2007) suggest that child care quality from birth through preschool does not predict behavior problems or other measures of social functioning in middle childhood. Similarly, results from the Cost, Quality, and Outcomes Study found no links between quality of child care during preschool and socioemotional functioning in second grade, although significant links were identified between teacher–child closeness during early child care and lower behavior problems during middle childhood (Peisner-Feinberg et al., 2001).

There is a notable paucity of research assessing the effects of child care quality on economically disadvantaged long-term behavioral functioning. Although the studies discussed earlier include children from a range of socioeconomic backgrounds, most children were from middle-class families. In contrast to the experiences of more affluent children, economically disadvantaged families tend to face high levels of stress and have limited resources to invest in children, leading to less stimulating, responsive, and emotionally supportive home environments (Magnuson & Votruba-Drzal, 2009). Such economic disparities have implications for children's development of behavior problems (Duncan & Brooks-Gunn, 1997; Votruba-Drzal, 2006). High-quality nonparental care settings may protect economically disadvantaged children by providing them with opportunities and experiences that facilitate the mastery of central developmental challenges in early and middle childhood (Dearing et al., 2009).

Model early intervention programs, such as the Perry Preschool Project and the Abecedarian Program, show that high-quality early child care experiences, combined with comprehensive services for children and families, protect low-income children against significant behavioral problems later in life such as juvenile delinquency and incarceration (Campbell, Ramey, Pungello, Sparlin, & Miller-Johnson, 2002; Schweinhart et al., 2005). These interventions were administered by highly trained professionals and provided multifaceted services to low-income children and families. In contrast, recent research indicates that the quality of child care typically experienced by economically disadvantaged children is highly variable and, indeed, often rated as inadequate in meeting children's developmental needs (Fuller, Kagan, Loeb, & Chang, 2004; Li-Grining & Coley, 2006), questioning the generalizability of results from such model intervention programs.

Virtually no studies have considered whether the quality of child care available in low-income communities provides long-term protection against behavior problems for economically disadvantaged children. The study by Peisner-Feinberg et al. (2001) found the protective effects of teacher–child closeness on behavior problems to be sustained more strongly among children of mothers with low education, which was used as a proxy for low income. Assessing low-income children from the Three-City Study, Votruba-Drzal, Coley, and Chase-Lansdale (2004) found that the quality of child care experienced by preschool-age children (average age of 3 years) predicted improvements in socioemotional functioning over a 1½ year period, with higher quality care reducing internalizing and serious externalizing behavior problems and enhancing positive behaviors. Similar results were reported by Loeb, Fuller, Kagan, and Carrol (2004) using a different sample of low-income children. It is unknown whether such short-term protective effects of child care quality on low-income children's behavioral functioning extend to middle childhood.

Extent of Child Care Use and Children's Behavior Problems and Socioemotional Functioning

Along with child care quality, the extent of nonparental care that children are exposed to is a salient dimension of early experiences in child care. Increasing evidence suggests that extensive experience in nonparental care during the early years may be harmful for behavioral functioning. Early, extensive nonparental care may threaten behavioral development by undermining maternal sensitivity, as mothers have less time to spend with young children and become familiar with their signals (NICHD ECCRN, 1999), or by imposing high levels of stress on young children associated with extended peer exposure that taxes their nascent self-regulatory and social skills. In a series of studies using data from the NICHD Study of Early Child Care, the NICHD ECCRN (1998, 2003, 2005) and Belsky et al. (2007) found positive links between the quantity of care children experienced and externalizing behavior problems during early childhood, although these effects faded out by middle childhood. Negative links also emerged between the hours children were in care and their social competence; these results remained through the transition to middle childhood (age 8) but faded thereafter becoming nonsignificant by the end of middle childhood (age 12). It is important to note that in the NICHD study, child care characteristics were measured from age 3 months through 54 months. The extent of care that children experienced across early childhood was quite stable, such that children who experienced extensive care during infancy tended to do so consistently throughout early childhood (NICHD ECCRN, 2003). Thus, NICHD measures of the quantity of care tap into both early entry and extensive hours of child care, and research with this sample has not been able to determine whether negative effects are due to early entry, to extensive hours of care, or to some combination of these two factors.

It is unknown whether a detrimental effect of extensive nonparental care will emerge among low-income children. Recent work assessing extent of child care during preschool years (e.g., after infancy but prior to kindergarten) has found no negative effects for low-income children. A recent study using a nationally representative sample found no detrimental effects of high hours in center care for low-income children's behavioral functioning in kindergarten, although negative effects were apparent among middle- and high-income children (Loeb et al., 2007). Similarly, longitudinal studies with low-income samples suggest no effects of extent of care (Love et al., 2003; Votruba-Drzal et al., 2004). One recent study of Canadian children found that an earlier age of onset of nonparental care (prior to 9 months) was protective against the development of externalizing behavior problems for children of mothers with low education, although the extent of care per week was not a significant predictor of behavior problems (Côté et al., 2007).

Type of Care and Children's Behavior Problems and Socioemotional Functioning

A third important aspect of early care experiences is captured by the type of care children experience, that is, care provided in child care centers or prekindergarten programs versus day care homes or informal care arrangements with relatives or babysitters. Formal child care centers typically have more educated care providers and higher developmental quality. Home arrangements, on the other hand, on average have notably smaller group size and lower child–adult ratios, often include relatives of the child as the care provider, and provide more flexible and accessible care to families (Coley, Li-Grining, & Chase-Lansdale, 2006; Li-Grining & Coley, 2006). Although beneficial for academic development, recent evidence with large and nationally representative samples suggests that center-based care is linked to elevated levels of externalizing problems in early childhood and that these associations are evident through middle childhood (Belsky et al., 2007; Magnuson et al., 2007). Although some argue that center-based care is less developmentally appropriate for infants in particular in comparison with home-based arrangements (Loeb et al., 2007), negative effects of center care on behavioral functioning have emerged when considering center care use in the preschool years (e.g., Magnuson et al., 2007) or including both infancy and preschool (e.g., Belsky et al., 2007). Although there is little research specifying the mechanisms of these effects, center-based care arrangements, with larger group sizes, fewer adults, and frequent staff changes, may challenge young children's self-regulatory skills and provide greater opportunities for negative peer interactions (Dowsett, Huston, Imes, & Gennetian, 2008). Recent studies have further argued that these harmful effects of center care on children's behaviors are stronger among poor children in comparison with their more advantaged counterparts (Loeb et al., 2007; Magnuson et al., 2007). It is interesting to note, however, that when studies are able to separate effects of child care quality, extent, and type, no detrimental effects of center care have been found for low-income preschoolers' behavioral functioning (Loeb et al., 2004; Votruba-Drzal et al., 2004). It is unclear whether such effects might emerge later during middle childhood.

Does Child Care Quality Matter More for Certain Children?

Bioecological theories of development suggest that individual characteristics may interact with environmental experiences to influence future development (Bronfenbrenner & Morris, 1998; Sameroff, 1994). In the realm of child care, we hypothesize that the effects of early experiences in nonparental care settings may differ based on characteristics of the developing child, such as gender and race/ethnicity. A variety of factors may lead to differential effects of early child care experiences on behavior problems related to child gender. These factors include gender differences in the development of inhibitory control (Kochanska, Murray, Jacques, Koenig, & Vandegeest, 1996) and in the nature of children's social interactions in same-sex peer groups (Fabes, Hanish, & Martin, 2003; Maccoby, 1998), as well as boys' overall greater vulnerability and reactivity to psychosocial stress (Zaslow & Hayes, 1986). If boys exhibit lower inhibitory control or greater peer conflict or show greater reactivity to stress, then the environmental challenges and opportunities imposed by nonmaternal care may have elevated effects on boys' psychosocial functioning.

A handful of recent studies have considered whether characteristics of nonpaternal care settings (e.g., quality, quantity, and type) are differentially related to children's behavioral functioning for girls versus boys. Most recent research has found no evidence of gender moderation in either the short or long term (Belsky et al., 2007; Burchinal, Peisner-Feinberg, Bryant, & Clifford, 2000; Peisner-Feinberg et al., 2001). On the other hand, recent research with low-income children from the Three-City Study found that high-quality child care appeared more protective for boys than girls when it came to the development of externalizing behavior problems, and low-quality care seemed to be especially risky for boys' development of serious internalizing behavior problems (Votruba-Drzal et al., 2004).

Another child characteristic that may moderate associations between early nonmaternal care experiences and the development of behavior problems in middle childhood is child race/ethnicity. Conceptual models highlight the importance of considering child care settings within the context of children's ethnic and cultural backgrounds, taking into account the ecological contexts of home and care settings (Johnson et al., 2003). A number of studies have reported race/ethnicity differences in the use of child care, with African American families more likely to access center-based care and Hispanics more likely to use informal kin care (Fuller, Holloway, & Liang, 1996; Radey & Brewster, 2007). Only recently has research begun to ask explicitly whether characteristics of child care settings (e.g., quality, type, and quantity) have differential effects on children's development across sociocultural contexts.

Two contrasting hypotheses have been proposed regarding child care effects across children from socioculturally diverse backgrounds. One argument is that high-quality child care can have an enhanced protective role for children experiencing risks from factors such as poverty, racial discrimination, immigration, or non-English-speaking status that might limit children's and families' access to economic and social resources. Similarly, poor quality child care may be particularly detrimental for such children. A contrasting argument suggests that child care settings may not meet the culturally specific needs of children from ethnic minority families (Burchinal & Cryer, 2003). Or, our current measures of child care quality may not be valid for ethnic minority children. These arguments would suggest that links between child care quality and child well-being would be attenuated among specific groups of ethnic minority children (Burchinal & Cryer, 2003).

Assessing two large, longitudinal studies of child care quality (the NICHD study and the Cost, Quality, and Child Outcomes Study), Burchinal and Cryer (2003) found support for neither argument. Rather, their results suggest that highly used measures of child care quality are equally valid and reliable across African American, Hispanic, and White samples, and furthermore that quality is similarly predictive of children's cognitive and socioemotional skills during the preschool years (see also Burchinal et al., 2000). It is important to note, however, that their samples had numerous limitations, particularly in regard to the percentage of Hispanic families, leading to questions concerning generalizability. In contrast, a recent study using data from the Early Childhood Longitudinal Study's Kindergarten Cohort (ECLS–K) found that center-based care was not related to heightened behavior problems among English-proficient Hispanic children but was a particularly strong predictor of behavior problems for African American children in kindergarten (Loeb et al., 2007). Furthermore, a third recent study found a particular aspect of child care quality, relationship-focused care, to be predictive of less adaptive functioning for Hispanic children but not related to functioning among African American children (Owen, Klausli, Mata-Otero, & Caughy, 2008). Together, these results suggest that the interactions between child care characteristics and children's ethnic backgrounds are complex and deserving of continued careful attention.

Research Aims

The current investigation aims to strengthen understanding of how low-income children's early education and care experiences shape their development into middle childhood. First, we will examine whether there are long-lasting associations between the developmental quality, extent, and type of child care settings low-income children experience and the development of their behavior problems into middle childhood. Second, consistent with the bioecological model of child development, we will explore whether associations between dimensions of child care settings and low-income children's development vary according to two key child characteristics—gender and race/ethnicity.

Method

Data for this article were drawn from the Three-City Study, a longitudinal, multimethod study of the well-being of low-income children and families in the wake of welfare reform. Two components of the Three-City Study were used: the main survey and the Embedded Developmental Study (EDS). The main survey was conducted with a household-based, stratified random sample of about 2,400 low-income children (aged 0–4 or 10–14 years) and their primary female caregivers in low-income neighborhoods in Boston, Chicago, and San Antonio. Three survey waves were conducted, in 1999 (90% screening rate and 83% interview completion rate), 2000–2001 (88% retention rate), and 2005 (80% retention rate from Wave 1). During each wave of the main survey, mothers participated in an in-home interview and children aged 2 and older completed individualized cognitive achievement assessments. The EDS portion of the Three-City Study provided a more intensive view into the lives of the preschool-aged children (2–4 years) from the main survey. The goal of the EDS was to capture rich detail about children's primary caregivers and early environments, assessed through additional mother interviews and videotaped assessments of mother–child interactions, biological father interviews, and observations of child care settings and interviews with child care providers. Children were eligible for the child care component of the EDS if they were in child care for 10 hr or more per week: 49% of 737 EDS children in Wave 1 and 40% of 670 children in Wave 2 were eligible. After obtaining permission from the mother and the child care provider, children were observed in their primary child care setting for at least 2 hr, and the child care providers were interviewed. The response rate for the child care component of the EDS was 70% in Wave 1 and 73% in Wave 2.

The current article is based on 349 families who participated in a child care observation at either Wave 1 or 2. Comparisons of the children in our sample to the broader sample of 2- to 4-year-olds in the Three-City Study revealed few significant differences, with the exception that the children in our sample were more likely to be African American and less likely to have parents who were employed and had slightly higher levels of education. Among the 349 children in the analytic sample, 5% were missing Wave 1 child behavior problems measures, 19% were missing a child care observation at one wave, 16% were missing data on at least one covariate, and 21% were missing Wave 3 child behavior problems measures. Our analysis of missing data suggested that the data were missing at random. Missing data were imputed using multiple imputation by chained equations implemented in Stata 10 (StataCorp, College Station, TX) to create 10 complete data sets (Royston, 2004, 2005), which were then analyzed using *mim* commands in Stata. Based on the relative efficiency calculation by Rubin (1987), 10 imputations were deemed sufficient for the level of missing data in our study.

Analytic Approach

A major challenge when considering child care's influence on children's development involves disentangling whether child care characteristics truly enhance development or whether it is simply the case that more advantaged parents have children who are more developmentally advanced and also choose higher quality child care. Certain characteristics of children and families, such as race/ethnicity, income, parental education and employment, social support, and children's age and gender, influence parents' decisions regarding child care (Fuller et al., 1996; Singer, Fuller, Keiley, & Wolf, 1998). Most studies have controlled for a variety of family differences that might influence both family decision making and children's development to isolate less biased estimates of child care's influence. Since it is impossible to measure all important family characteristics, an additional strategy is to limit the influence of unmeasured variables statistically.

In the current analyses, associations between child care characteristics and the development of behavior problems in middle childhood were modeled using a longitudinal lagged regression model that is based on an accumulation of inputs framework, which has been articulated most clearly in the work of NICHD ECCRN and Duncan (2003) and Blau (1999). This model suggests that child *i*'s development at time *t* is an additive function of all child care, maternal, child, and household inputs to a child's development prior to that point in time. So, for example, as shown in Equation 1, behavior problems during middle childhood (Wave 3) are expressed as a function of child care characteristics, including the type of care arrangement, number of hours spent in care, and the quality of the care that children have experienced across Waves 1 and 2 of the study.

$$\begin{aligned}\text{Child outcomes}_{3i} = B_0 &+ B_1\,\text{child outcomes}_{1i}\\ &+ B_2\,\text{child care}_{1-2i}\\ &+ B_3\,\text{maternal}_{1-2i}\\ &+ B_4\,\text{child}_{1-2i} + \varepsilon_i. \qquad (1)\end{aligned}$$

To reduce the threat of selection bias posed by measured characteristics of children and families, a series of child, maternal, and household factors aggregated over Waves 1 and 2 of the survey were included in the models as covariates. Covariates included child age, gender, and race/ethnicity as well as maternal education, employment, and marital status. Each of these factors has been associated with characteristics of early care experiences and behavior problems in prior research. Thus, the failure to include these variables in our analysis may result in omitted variable bias. A Time 1 measure of the same child outcome that was being modeled as the dependent variable at Time 3 was included as an additional covariate in the model to reduce omitted variable bias further. The regression coefficients are thus interpreted as the effects of each independent variable on changes in behavior problems over time (Kessler & Greenberg, 1981). Including the Time 1 child outcome as a covariate allows us to control for unmeasured, time-invariant differences in children that were present at the first interview (Cain, 1975; Chase-Lansdale et al., 2003). In this model, unmeasured, time-varying characteristics of children that may be related to child care selection at Time 1 or 2 and children's development over time may continue to bias estimates of the relation between child care characteristics and children's development.

In addition to considering main effects of child-care experiences, we explored whether or not the effects of child care type, extent and quality vary as a function of a child's gender and race. This was done by adding interactions between child care characteristics and both child gender and race/ethnicity to our model followed by a series of post hoc regression analyses to compare the nonreference race/ethnic groups. All analyses were weighted with probability weights, which strengthen our ability to make inferences to our population of interest, which includes all children living in low-income neighborhoods in Boston, Chicago, or San Antonio in households with incomes < 200% of the poverty line.

Measures

Child care characteristics The global developmental quality of each child's care arrangement was measured during child care observations at Waves 1 and 2 using widely used and well-validated instruments. Center-based care arrangements were rated using the Early Childhood Environment Rating Scale–Revised (ECERS–R; Harms, Clifford, & Cryer, 1998). The quality of day care homes and informal home care arrangements was measured using the Family Day Care Rating Scale (FDCRS; Harms & Clifford, 1989). Fifteen percent of the observations were independently double-coded, with average intraclass correlations (ICC) at the subscale level of .90 in Wave 1 and .89 in Wave 2 for the ECERS–R and .98 and .99 for the FDCRS. The Arnett Scale of Provider Sensitivity (Arnett, 1989) was used to measure the emotional and behavioral relationships between the care providers and children in both center- and home-based care arrangements. The Arnett Scale (α_{T1} = .94 and α_{T2} = .92) supplemented items related to the teacher–child relationships on the ECERS and FDCRS, which focus more on supervision and discipline. Composite scores had average ICCs of .81 and .82 at Waves 1 and 2. A global child care quality composite (α_{T1} = .94 and α_{T2} = .91) was created at each wave by combining subscales from the ECERS or FDCRS with the composite score from the Arnett (Growing Up in Poverty Project, 2000; Votruba-Drzal et al., 2004). The total quality scores from Waves 1 and 2 were then averaged to reflect the average level of child care quality that children experienced across the first two waves of the study.

The extent of child care children experienced was measured using maternal reports of the number of hours per week that children were in child care at Waves 1 and 2 of the survey. These numbers were then averaged to create a composite measure of the extent of care that children experienced across Waves 1 and 2 of the survey. Child care type was coded with dummy variables indicating whether children experienced consistent center care across both waves of the survey, center care at one wave only, or consistent home-based care across Waves 1 and 2 (omitted).

Behavior problems Behavior problems were measured using mothers' reports on the age-appropriate version of the Child Behavior Checklist (CBCL; Achenbach, 1991, 1992; Achenbach & Rescorla, 2001). Analyses focused on the internalizing and externalizing behavior problems subscales. The CBCL internalizing scale (αs = .83–.87) focuses on anxiety, depression, withdrawal, and somatic complaints, whereas the externalizing scale (α_{T3}s = .90–.91) includes items related to aggression and rule breaking. Standardized (*T* scores) subscale scores from Wave 3 were used as dependent variables, with scores from Wave 1 included as covariates to reduce bias related to unobserved heterogeneity. We also included an indicator for whether the 2- to 3-year-old version or the 4- to 18-year-old version of the CBCL was used in Wave 1, to control for differences in instrumentation.

Child characteristics. Child characteristics included as covariates included child age at Wave 3 represented in months, and gender. Child race was represented with a series of dummy variables indicating whether the child is of Hispanic (omitted), non-Hispanic African American, or White/other non-Hispanic origin. Child characteristics were obtained via mother report.

Maternal and household characteristics. Several maternal and household characteristics averaged across Waves 1 and 2 were also included as covariates. Covariates included maternal education (greater than a high school education vs. a high school degree or less), employment (employed at least 10 hr per week vs. not), and marital status (married vs. not). Characteristics of children and mothers are presented in Table 1 along with descriptive information about their child care arrangements. Children in the analytic sample averaged 3 years of age in the first wave (range = 2–5 years) and averaged 9 years of age in the third wave (range = 7–11). They were primarily African American (55%) and Hispanic (37%), and most lived with single mothers (84%) with relatively low education. Bivariate correlations of the child care and behavior problems variables are available from the first author by request.

Results

Child Care Characteristics and Low-Income Children's Development in Middle Childhood

Results from lagged ordinary least squares regressions on children's behavior problems in middle childhood (i.e., at Wave 3) are presented in

$^{\dagger}p < .10$. $^{*}p < .05$. $^{***}p < .001$.

Table 2. Child care quality was linked to significant reductions in externalizing behavior problems over time. The magnitude of this association was modest in size. A 1 SD increase in the child care quality composite was linked to .26 of a standard deviation decline in externalizing behavior problems. The association between child care quality and internalizing behavior problems in middle childhood was also negative and of a relatively similar size (.15 of a standard deviation) but failed to reach conventional levels of statistical significance ($p = .10$). Controlling for the quality of care, neither the type of child care that children experienced nor the extent of care were significantly related to the development of behavior problems in middle childhood.

The relatively high correlation between stable center care and average quality in our data ($r = .47$) is consistent with the literature on child care for low-income families but raises concerns when the measures are analyzed simultaneously in a regression model. Thus, we ran an additional set of model specifications to consider whether the quality findings hold when the measure of child care type is excluded from the models and to confirm that we do not detect a significant effect of center care when child care quality is dropped from the model. When the measure of child care type was dropped from the regression models presented in Table 2, the negative effects of child care quality on both internalizing ($B = -1.62$, $t = -2.31$, $p < .05$) and externalizing ($B = -2.15$, $t = -2.81$, $p < .01$) behavior problems strengthened slightly. When child care quality was excluded from the models presented in Table 2, associations between child care type and both internalizing and externalizing problems remained nonsignificant at conventional levels, although stable center care did predict declines in internalizing problems at a level bordering significance ($B = -4.07$, $t = -2.08$, $p = .05$). This set of specifications helps strengthen our certainty that child care quality is the predominate factor in our models protecting against the development of behavior problems during middle childhood.

Child Characteristics as Moderators

The second set of analyses considered whether associations between child care characteristics and children's development varied as a function of child gender and race/ethnicity. Before delving into the results of these analyses, it is important to consider whether there are significant differences related to child gender and race/ethnicity when it comes to our primary variables of interest. There were no significant differences in average levels of behavior problems by gender or race/ethnicity at Wave 1 or 3. Nor were there significant differences in average child care characteristics by child gender. Characteristics of child care experiences were similar by race/ethnicity as well, with the exception that the average level of child care quality of children falling into the White/other race/ethnic category was significantly higher than the average level of quality for both African American and Hispanic children.

Child care characteristics and gender. Regression results indicated that child gender moderated the link between child care quality and children's functioning (see Table 3). Specifically, high-quality child care appeared to be especially protective for boys' development of internalizing behavior problems. The results for externalizing behavior problems suggest a similar pattern, but the interaction term did not reach statistical significance. A standard deviation increase in the child care quality composite was associated with .37 more of a standard deviation decline in internalizing behavior problems for boys when compared to girls. There was also some evidence to suggest that child care type showed different patterned links with boys' and girls' behavior problems, with a tendency for center care (i.e., one wave of center care and two waves of consistent center care) to be more protective for girls than boys when it came to the development of internalizing problems, when comparing center care to home-based care. This same pattern emerged for externalizing behavior problems, but this interaction was not statistically significant. Finally, consistent with the results of the main effects models, no significant associations were observed between the extent of child care and the development of behavior problems for boys or girls.

Child care characteristics and race/ethnicity. The association between child care quality and behavior problems in middle childhood also varied as a function of race/ethnicity. The results presented in Table 3 show that child care quality seemed to be especially protective against the development of behavior problems among African American children. Greater child care quality was related to significantly greater reductions in externalizing behavior problems for African American children than for both Hispanic and White/other children. Although this interaction between child care quality and child race/ethnicity did not reach statistical significance for internalizing behavior problems, the same pattern of results emerged.

Discussion

Utilizing multimethod data from a representative sample of young children in low-income neighborhoods, this study extends existing research by assessing longer term effects of child care characteristics on the development of behavior problems through middle childhood. In this analysis, we asked whether three aspects of child care experiences predicted behavior problems: the global developmental quality of care, the extent of care, and care type. It is important to note that in this study, we assessed children's experiences in child care during their preschool years; the data did not include information on nonparental care during infancy.

The Importance of Child Care Quality

The most consistent results from this analysis highlight the importance of the quality of care in the reduction of problem behaviors. Using well-validated, standardized observational measures of the global developmental quality of the care provided by child care settings and controlling for the type and extent of care, we found that higher quality care was protective against the development of behavior problems in middle childhood. Children who attended more responsive, stimulating, and well-structured care settings than their peers during their preschool years showed reductions in externalizing behavior problems by mid-elementary school. The pattern of results was similar for internalizing behavior problems, although insufficiently precise to reach statistical significance. This means, of course, that the reverse was true as well: Children attending lower quality child care showed more elevated behavior problems than their peers by mid-elementary school.

These results extend a very limited and contradictory base of research concerning whether child-care quality shows longer term links with socioemotional functioning into middle childhood. Peisner-Feinberg et al. (2001), for instance, found positive effects of close teacher–child relationships but not global developmental quality on second graders' social functioning, whereas other research has unearthed longer term benefits of high-quality care on cognitive skills but not socioemotional functioning into middle childhood. For example, the NICHD study found that high-quality care from birth through age 5 predicted higher cognitive scores in third and fifth grades (Belsky et al., 2007; NICHD Early Child Care Research Network, 2005), but found no effects on behavior problems or socioemotional functioning among their notably more advantaged sample.

Why might our results differ so substantially from those derived from more economically advantaged samples? A risk and resilience framework may be useful in reconciling these differences (Masten, Best, & Garmezy, 1990). Children in our sample, primarily from ethnic minority, single-parent families with extremely limited economic resources and residing in high-poverty urban neighborhoods, likely faced an accumulation of risks across multiple contexts. Although most children have the resources to cope with one risk without serious developmental consequences, the cumulative risk perspective suggests that the accumulation of risk across settings leaves children vulnerable to maladaptive psychosocial functioning (Friedman & Chase-Lansdale, 2002). Faced with contextual risks from multiple sources, high-quality, responsive, and stimulating child care settings may serve as a protective factor, or source of resilience, for young children to avoid problematic behavior and to develop nascent emotional and behavioral skills in self-regulation, peer interactions, and conflict management during their early school years. Similarly, low-quality child care may exacerbate the existing risks children experience. Indeed, it is interesting to note that the current results show stronger and more consistent effects of child care quality on behavior problems than found by Votruba-Drzal et al. (2004) looking at short-term effects predicting children's well-being during early childhood.

A second set of core findings from this study indicated that particular subgroups of children were driving our findings related to child care quality. Based upon bioecological theory that suggests that the effects of contextual experiences may differ in response to characteristics of the individual, we hypothesized that child gender and race/ethnicity may moderate links between child care and children's development of behavior problems. Our results supported this hypothesis. Regarding gender, our findings suggest that higher quality early education and care experiences were particularly important for boys. Child care quality more strongly predicted a decline in boys' than girls' internalizing behavior problems, and a similar pattern of results was evident for externalizing problems although it was not statistically significant. The behavior problems of boys may be more responsive to the quality of their early nonmaternal care arrangements due to their greater challenges with self-regulation, wherein boys tend to have lower levels of inhibitory control and physiological regulation than girls (Dettling, Parker, Lane, Sebanc, & Gunnar, 2000; Kochanska et al., 1996). Moreover, during preschool, boys' peer interactions appear to incorporate more conflict and roughness than girls' play, with the latter involving more verbal interactions and cooperation (Fabes et al., 2003; Maccoby, 1998). Thus, as noted by Votruba-Drzal et al. (2004), more responsive and well-structured child care settings may provide an important support to boys in helping to regulate their behaviors and emotions and supervise their play in a productive manner.

In addition to this gender moderation, results also found that race/ethnicity was important. More specifically, child care quality was particularly protective against the development of behavior problems for African American children when compared to Hispanic and White/other children. When they were cared for in high-quality settings, African American children experienced greater declines in externalizing behavior problems than both Hispanic and White/other children. The same pattern of results emerged for internalizing problems, although the interactions were not statistically significant. These results may be related to the greater acceptance and wider use of formal child care and maternal employment among African American children, resulting in a better match between families' goals and expectations and child care settings. As noted by Johnson, Jaeger, Randolph, Cauce, Ward, and NICHD ECCRN (2003), in understanding ethnic minority families' experiences in child care, we must attend to their broader cultural and ecological contexts. Based upon theories of person-environment fit and models of competency in children of color (Garcia Coll et al., 1996; Johnson et al., 2003), this conceptualization argues that children's development must be understood in context, with minority children's contexts affected by their social and cultural location. Hispanic families may have fewer social norms concerning maternal employment and nonmaternal care provision; they also may experience greater disconnects between the language environment of child care settings and home settings (Magnuson & Waldfogel, 2005). Indeed, other research has found that Hispanic parents, particularly in immigrant families, are less likely to access a broad range of social services in addition to formal child care and these restrictions are linked with poorer outcomes for children (Kalil & Chen, in press).

If the context of the care setting provides a stronger fit with the family preferences and cultural norms of African American children, whereas language or cultural disconnects between home and care settings inhibit person–environment fit for Hispanic children, we would expect that supportive characteristics of care settings such as high-quality, structured, responsive care giving would have a stronger beneficial effect on African American children's development. Supporting the tenets of bioecological theory, this proposition argues that environmental experiences (e.g., child care) are both affected by and interact with individual characteristics of the child and family. Indeed, other research with the Three-City Study child care sample found that African American mothers reported greater satisfaction with their child's care setting than did Hispanic and White mothers, and also reported (nonsignificantly) higher levels of communication and comfort with the care provider (Coley et al., 2006). Future research should seek to explore these interactions more closely, for example assessing whether a match between the language or ethnicity of the care provider and the child improves the quality of the child's care experiences and enhances the beneficial effects of high-quality care or the detrimental effects of early entry or long hours in nonparental care settings on children's development.

It is interesting to note that the stronger beneficial effects of child care quality for African American than for Hispanic children found in the current research contrast with a lack of ethnic moderation found in larger scale studies assessed by Burchinal and Cryer (2003). As the authors remind us, those larger scale studies included extremely small samples of Latino families and excluded families who were not fluent in English. They also had small groups of low-income families. Although our sample is smaller, it is representative of low-income families in our three cities, and includes both English- and Spanish-speaking Hispanic children, with approximately 20% of children residing in immigrant families. It is possible that this more representative sample of low-income, ethnic minority children was better poised to unearth important ethnic differences in the effects of child care on children, over a longer time period. Given the paucity of research in this arena and the continuing notable expansion of ethnic diversity in the United States, continued assessment of ethnic and cultural variation in child-care effects on child well-being is clearly warranted.

Limited Results for Child Care Type and Extent

In addition to the quality of child care, this study also assessed the effect of child care type and the extent of use. As mentioned previously, studies using data from the NICHD Study of Early Child Care and Youth Development (SECCYD) and the ECLS–K have uncovered harmful effects of extensive or early-initiated child care on behavior problems, some of which endure in middle childhood (Belsky et al., 2007; Loeb et al., 2007). Similarly, these studies have found that the use of center-based care is linked with heightened behavior problems continuing into elementary school, albeit also with enhanced cognitive skills (Belsky et al., 2007; Loeb et al., 2007; Magnuson et al., 2007; NICHD ECCRN & Duncan, 2003). These patterns were not replicated in this study. Categorizing children's preschool experiences over two waves as being housed consistently in home-care settings, consistently in formal center care, or inconsistently in center care, and measuring the hours per week children experienced child care, we found that neither care type nor extent were linked to behavior problems in middle childhood. One exception to this pattern was a trend finding that suggested that center care in comparison with home-based care may be beneficial for girls but not boys when it comes to the development of internalizing problems.

In comparing these results to other longitudinal studies, it is important to note that we did not assess hours of care or center care starting in infancy but focused only on the preschool years. Extensive and large-group care settings may be more taxing for infants and toddlers than preschool-age children. Moreover, returning to the risk and resilience perspective noted earlier, it is possible that for children in high-poverty neighborhoods and families, the challenges of center care or extensive child care may not pose a measurable burden in isolation. Facing enhanced rates of residential moves and relationship transitions in comparison with advantaged families, poor children may react in a less discernable fashion to the extent and type of child care, with process variables like quality holding greater importance. Indeed, a previous shorter term study with the Three-City Study sample found that extent of care was linked with behavior problems only in interaction with the quality of care: More extensive experience in high-quality care predicted decreased behavior problems, whereas extensive experience in low-quality care predicted increases in behavior problems (Votruba-Drzal et al., 2004).

Conclusions

This study provides an important addition to existing research on child care arrangements and children's developmental trajectories. Overall, our results highlight the importance of the developmental quality of care experiences for disadvantaged young children, arguing that high-quality child care experiences can have a sustained influence on children's behavioral functioning, through their transition to formal schooling and into middle childhood. Early child care quality is important for understanding low-income children's ability to function effectively in school, get along with their peers, and control their impulses. Future research should seek to assess a broader array of behavioral and emotional functioning measures, for example, assessing prosocial behaviors and social skills.

This study has several strengths. One is the sampling of the Three-City Study, which provides an in-depth look at a representative sample of young children and their families living in economic disadvantage, at both the family and community levels, in three cities. As such, this sample, whose experiences of urban poverty place children at notable risk for maladaptive social functioning, represents a population of significant concern to policy makers and practitioners. Increasing understanding of what types of supportive services can enhance the well-being of such children is of paramount importance for practitioners and policy makers. Moreover, our study focuses on children and families' experiences in community care, which are the care settings that disadvantaged parents have been able to access in their communities. Although model early intervention studies have provided centrally important information on how to productively intervene and provide bundles of high-quality services to disadvantaged families, such studies cannot tell us whether their findings can be generalized to the types of services to which disadvantaged families actually have access.

It is also important to point out limitations of the current study. As in all nonexperimental work, we cannot draw causal conclusions from the results and remain cognizant that the links detected here, between child care environments and children's developmental trajectories, could be due to selection or other unmeasured variables. The inclusion of child and family characteristics as well as earlier child functioning lessens the likelihood of such alternative explanations. Still, we were not able to control for characteristics of important contexts, such as schools and homes, in the years between preschool and middle childhood. If these were correlated with child care characteristics, this would threaten the validity of our results. The analytic sample was also relatively small and representative of a particular population of disadvantaged urban families. Although attention was paid to carefully measuring characteristics of both child care centers and more informal home arrangements, this study was not able to compare children's experiences in maternal care to those of their peers in child care settings. Continued careful analysis of early child care environments and children's development using diverse samples and multiple methods that include measures of both behavior problems and social competence will help the field to triangulate evidence of how child care can support low-income children's healthy development. Further studies can also more carefully assess individual children's experiences in child care settings (rather than a more global classroom and group-level assessments obtained through measures such as the ECERS, FDCRS, and Arnett). Such research might shed light on the differential patterns related to child gender and ethnicity unearthed here.

Finally, studies have raised questions about the validity of the CBCL for high-poverty or ethnic minority children and the results of these studies are mixed. Some have validated the CBCL with low-income, African American, and Latino families (Gross et al., 2006; Sivan, Ridge, Gross, Richardson, & Cowell, 2008), whereas others have uncovered problems with using CBCL norms for these populations (Raadal, Milgrom, Cauce, & Mancl, 1994; Sandberg, Meyer-Bahlburg, & Yager, 1991). Thus, it is important for our findings to be replicated using alternative measures of behavior problems.

In sum, this article is part of a new generation of child care research that is taking a more nuanced approached to multiple dimensions of children's experiences in child care. With a sizable sample, valid, reliable, and longitudinal measures and rigorous statistical methodology, we have increasing confidence that child care quality is an important factor in the developmental trajectories of young children in poverty. The results of the present study add to a growing body of empirical evidence suggesting the need for policy and programmatic efforts to increase low-income families' access to high-quality child care.

Children's Understanding of Ordinary and Extraordinary Minds

Jonathan D. Lane, Henry M. Wellman, and E. Margaret Evans
University of Michigan

How and when do children develop an understanding of extraordinary mental capacities? The current study tested 56 preschoolers on false-belief and knowledge-ignorance tasks about the mental states of contrasting agents—some agents were ordinary humans, some had exceptional perceptual capacities, and others possessed extraordinary mental capacities. Results indicated that, in contrast to younger and older peers, children within a specific age range reliably attributed fallible, human-like capacities to ordinary humans and to several special agents (including God) for both tasks. These data lend critical support to an anthropomorphism hypothesis—which holds that children's understanding of extraordinary minds is derived from their everyday intuitive psychology—and reconcile disparities between the findings of other studies on children's understanding of extraordinary minds.

Children and adults worldwide come to understand persons as intentional agents who act in accordance with their perceptions, desires, and beliefs (Flavell & Miller, 1998; Wellman, 1990). Most people also come to entertain ideas about nonhuman or superhuman agents with extraordinary mental capacities (such as deities who are all-knowing) or agents with exceptional perceptual capacities (such as animals with specialized senses or superheroes with X-ray vision). How and when do such concepts of extraordinary or exceptional agents develop? Addressing this question promises to inform fundamental issues in cognitive development, such as the nature of intuitive and counterintuitive ideas, the enculturation of thought, and the cognitive foundations of religion.

Arguably, the ability to appreciate extraordinary or exceptional capacities originates in early childhood and is intimately linked to the development of an understanding of ordinary, human capacities. Children's understanding of persons and minds —their *theory of mind*—undergoes substantial development during the preschool years (Wellman & Liu, 2004), as children increasingly appreciate the subjective nature of perceptions and thoughts. Such development requires that children disambiguate how the world really is from how self and others perceive and think about the world. Very young children have difficulty understanding this distinction between appearance and reality. When asked about what other people know or believe, very young children tend to answer by simply assessing reality and using that information to infer others' knowledge and beliefs (Wellman, Cross, & Watson, 2001). We refer to this tendency as a *reality bias*.

One early-emerging manifestation of children overcoming this reality bias is their understanding of *ignorance*—an understanding that agents can be unaware of certain facts. By 3 years of age, children understand that ignorance may result from a variety of circumstances, including agents' lack of perceptual access to certain information. For example, older 3-year-olds understand that only those individuals who have looked inside a container will know what the container holds (Pillow, 1989; Pratt & Bryant, 1990). Soon after children develop an appreciation for the distinction between knowledge and ignorance, they begin to appreciate the distinction between reality and belief; they start to understand that others, misled by inaccurate perceptual cues or outdated information, can hold *false beliefs* (Wellman & Bartsch, 1988). In one standard false-belief task—an unexpected contents task (Perner, Leekam, & Wimmer, 1987)—children are shown that a familiar container (e.g., a cracker box) holds something atypical (e.g., rocks). The container is then closed and children are asked what another person, who has not seen in the container, will

think is inside. When faced with this task, 3-year-olds typically report that the other person will think the cracker box contains rocks, demonstrating a reality bias. Older 4-year-olds, in contrast, report that others will think the box contains crackers, demonstrating their ability to distinguish how the world really is from one's beliefs about the world.

Thus, in the preschool years, children evidence an emerging understanding of human knowledge and beliefs, including some appreciation of mechanisms that yield knowledge and beliefs (e.g., that seeing leads to knowing). But how does an understanding of the mental capacities of nonhuman or superhuman agents emerge? Studying children's developing understanding of extraordinary minds is interesting in its own right and also promises to shed light more generally on children's understanding of ordinary minds. One possibility, stemming from Piaget's (1929/1979) notion that preoperational children anthropomorphize all agents, has been termed the *anthropomorphism hypothesis*. According to this hypothesis (Boyer, 1996), when children first come to attribute constrained knowledge and fallible beliefs to ordinary humans, they attribute similar limitations to all agents. Only later, building on this initial platform, do children differentiate between the limited capacities of ordinary humans and extraordinary agents' less limited capacities.

An anthropomorphism hypothesis is intuitively appealing; even adults tend to think of nonhuman beings, such as God, as human-like (Barrett & Keil, 1996; Gray, Gray, & Wegner, 2007). Indeed, although formal religious doctrine may attribute radically nonhuman, counterintuitive capacities to deities (e.g., total omniscience), in everyday judgments adults tend to think of deities in terms that are more human-like and limited, and thus only moderately counterintuitive (Barrett, 2000; Boyer, 1996, 1998). For example, Barrett and Keil (1996) found that even religious believers well versed in God's omniscience conceptualized God as attending to people's prayers sequentially, rather than attending to all prayers simultaneously, suggesting that they thought of God as subject to some of the same spatiotemporal constraints as humans. If such anthropomorphic tendencies are true of adults, they seem all the more plausible for children.

However, seminal studies by Barrett, Richert, and Driesenga (2001) challenged this anthropomorphism perspective. These researchers asked children (who attended Christian preschools) to reason about the knowledge and beliefs of humans, God, animals, and inanimate objects. In two studies, using unexpected-contents false-belief tasks, 3- to 7-year-olds reported what their mother, a tree, nonhuman animals, and God would think is inside a cracker box that contained rocks. Regardless of age or level of false-belief understanding, children typically reported that God would know the actual contents of the box. In another study, these researchers asked 3- to 8-year-olds whether a human, a monkey, God, or a cat that could see in the dark would know the contents of a box that had only a small slit to peer inside and no internal illumination. Children consistently reported that God and the cat would know the contents of the box, both before and after they gained an understanding (at about age 5 years) that humans and monkeys would not know the contents of the box.

Based upon these findings, Barrett and colleagues (Barrett & Richert, 2003; Barrett et al., 2001) have endorsed an alternate *preparedness hypothesis*, which states that "early-developing conceptual structures in children used to reason about God are *not* specifically for representing humans, and, in fact, actually facilitate the acquisition and use of many features of God concepts of the Abrahamic monotheisms" (Barrett & Richert, 2003, p. 300). Further, Barrett et al. (2001) proposed that, "children can have a more accurate understanding of God's agency than that of humans" (p. 54). That is, very young children's tendency to *not* attribute false-beliefs or ignorance to any agent reflects an early supposition of infallible mental capacities; children treat all agents (human and nonhuman) as omniscient. This hypothesis thus advances the intriguing idea that early cognitive biases facilitate rapid awareness of certain counterintuitive ideas, including ideas about the extraordinary qualities of God.

Although intriguing, these findings and the preparedness hypothesis raise several questions, both empirical and conceptual. First, when very young children apparently attribute infallible knowledge and beliefs to persons (or Gods), their answers may simply reflect an early reality bias—they answer by reporting the reality of the situation without considering agents' mental abilities (Evans & Wellman, 2006; Wellman & Bartsch, 1988). The critical question then is what children attribute to God when they *first* start to distinguish between the actual state of reality and people's (often inaccurate) mental representations of that reality; in particular, at the point when they begin to attribute false beliefs or ignorance to humans. At that point, do they attribute fallible knowledge and beliefs to God as well, as proposed by the anthropomorphism hypothesis, or infallible knowledge and beliefs, as implied by the preparedness hypothesis? At a later age, when children have developed a more robust understanding of fallible mental capacities, around 5 to 6 years of age, both preparedness and anthropomorphism hypotheses might predict that children attribute more infallible mental capacities to God, provided they have been exposed to such information about God. The preparedness hypothesis predicts that such an understanding at age 6 would reflect a *continuation* of children's early default understanding of extraordinary minds. The anthropomorphism hypothesis, in contrast, posits that such an understanding at age 6 indicates that children are beginning to loosen their earlier tendencies to anthropomorphize all agents. To best test these two hypotheses, it is necessary to densely sample children within the proper age range. Further, the data should be analyzed in a sensitive age-related fashion in order to find and assess the critical window when children *first* correctly attribute fallible mental capacities to humans. Barrett et al. (2001) simply grouped 3-, 4-, and 5-year-olds in year-long age blocks that might have masked the critical developmental window during which children first begin to ascribe human-like limitations to nonhuman agents for these social-cognitive tasks.

A second empirical issue concerns the replicability of Barrett et al.'s (2001) findings. This may well be related to the first issue of fine-grained age sampling and analyses, because different samples or different age groupings may differentially capture the critical developmental window. On the one hand, Barrett and colleagues (Knight, Sousa, Barrett, & Atran, 2004) have replicated their findings with a sample of Yukatek Mayan children whose culture has adopted the Catholic God. As well, Richert and Barrett (2005) reported data conforming to a preparedness trajectory for children's performance on a diverse set of knowledge-ignorance tasks. But other researchers offer findings that conflict with those of Barrett and colleagues, and which would be better explained by the anthropomorphism hypothesis (e.g., Giménez-Dasí, Guerrero, & Harris, 2005; Makris & Pnevmatikos, 2007). For example, using a less challenging knowledge-ignorance task, Makris and Pnevmatikos (2007) found that 3- and 4-year-olds reliably attributed ignorance both to a human and to God. These latter findings suggest that, at least for certain mental properties, there may be a developmental period during which young children concurrently believe that human and nonhuman mental capacities are constrained.

Alongside these empirical issues is an important conceptual one. When children attribute accurate knowledge to God in a false-belief or knowledge-ignorance task, how are they reasoning about such knowledge and beliefs? One interpretation, following from the preparedness hypothesis, is that they are attributing (and prepared to attribute) to God something like omniscience—the capacity to know all things without perceptual access. But the tasks used tell us little about children's appreciation for the mechanisms through which agents acquire their knowledge or beliefs. In past studies, it is unclear whether young children (even 5-year-olds) attributed to extraordinary agents privileged knowledge directly or via certain (ordinary or exceptional) mechanisms. For example, children may have assumed that God had special visual capacities (a moderate extension of human capacities) and thus actually *saw* the contents of the containers. Indeed, Richert and Barrett (2005) found that children as young as 4 years understood that agents with specialized senses (e.g., exceptional hearing or vision) can gain knowledge about certain stimuli that would be elusive to normal humans. Thus, one unaddressed issue concerns when exactly children are able to understand that an agent can possess certain (privileged) knowledge or beliefs *without* the use of perceptual mechanisms. And this is related to whether and when they might attribute anything like omniscience to God.

We addressed these empirical and conceptual issues in several ways. We employed fine-grained age sampling and analyses (on the order of months rather than years) in an effort to reveal, more precisely, the ontogenetic unfolding of concepts of extraordinary minds. We tested children on both false-belief and knowledge-ignorance tasks and, because children develop an appreciation for human agents' ignorance and false beliefs on different timetables, we analyzed the age-related trajectories for these two tasks separately with appropriately different age groupings. Further, and crucially, we addressed the conceptual issue about children's understanding of mechanisms mediating ordinary and apparently extraordinary knowledge and beliefs. Our primary method was to present 3-, 4-, and 5-year-olds with carefully contrasting agents. Specifically, we asked children to report on the mental capacities of ordinary humans (their mother and a young girl), and various nonhuman and superhuman beings, including God. In some cases, we carefully specified, for the child, the capacities and mechanisms possessed by the agent. Two agents were specified as having special perceptual mechanisms for acquiring knowledge: a cat that can see in the dark and a superhero

(Heroman) who possesses X-ray vision. One other agent (Mr. Smart) was described as being able to "know everything," even without seeing, so Mr. Smart's knowledge or beliefs did not depend on perceptual mechanisms at all.

Each of these "special" agents was described in a brief but detailed way (see the Appendix). Mr. Smart's and Heroman's special powers were also elaborated through brief demonstrations. Note that Mr. Smart was of interest in his own right and also served as a control in relation to God. It is impossible to know the precise information each child had already received about God and surely children did not have equal exposure to tutelage about a sentient God or God's extraordinary attributes. Therefore, in contrast to God, about whom we provided no information, for Mr. Smart we gave all children exactly the same background information regarding his attributes. If, as predicted by the preparedness hypothesis, children are prepared to pick up on such information, given prior tendencies to think of agents as infallible and all-knowing, then Mr. Smart should be especially easy to appreciate. This set of contrasting agents allowed us to assess the extent to which children appreciated different mental and perceptual capacities as well as the specific mechanisms agents may use to gather information. As a second method for generating information about children's reasoning about mechanisms, we asked children to explain their judgments. For example, if they judged that an agent knew the contents of a completely darkened container, we asked them how that agent knew that information.

Method

Participants

Fifty-seven children (32 males), ranging in age from 40 to 73 months (*M* age = 54 months), participated. Primarily, children were of European American descent and lived in a middle- to upper-middle-class Midwestern university community. We densely sampled children in a critical age range (50–56 months) on the hypothesis (established during pilot testing) that, during this period, children would be likely to first understand ordinary humans' limited mental and perceptual capacities. One child was excluded from the sample because she could not remember the actual contents of the box for the knowledge-ignorance task. Following the interview, when asked what they knew about God, more than half of these children (59%) provided specific details about God (e.g., "He's very smart," "He's magical and powerful"). Thirty-nine parents agreed to briefly report on their child's exposure to religious concepts. Almost half of these parents reported that they take their child to a place of worship, most on a weekly or monthly basis.

Procedure

Children were interviewed individually in a quiet location. They were asked about the beliefs and knowledge of various agents (see the Appendix) using two tasks: one a contents false-belief task (Perner et al., 1987) and the other a knowledge-ignorance task (similar to that used by Barrett et al., 2001). Half of the children received the false-belief task first; the others received the knowledge-ignorance task first. Each of the agents was displayed on a 5 × 7 in. laminated card. Importantly, prior studies have shown that children perform equally well on these tasks whether the protagonists are drawings, puppets, or live performers (Wellman et al., 2001). Children were introduced to each agent (see precise language in the Appendix) upon their first exposure to that agent. For each task, children were presented either mom or the girl first. The presentation of the remaining agents was randomized (the girl or mom was presented as the second agent for 2 children, only).

Because prior research suggests that adults who are exposed to anthropomorphic images of God are more prone to make anthropomorphic judgments about God (Barrett & VanOrman, 1996), we assessed whether the presentation of an image representing God would influence children's judgments about God's mental capacities. Thus, half of the sample was tested using a blurry nondescript image to represent God (see the Appendix), and the other half received no image and no language alluding to a bodily presence for God.

Measures

False-belief understanding. Children were shown a crayon box and a brown paper bag. The experimenter asked children what they thought was inside the crayon box and then showed them that the box actually held marbles and that the paper bag held crayons. Both containers were closed, and as a memory check, children were asked which container had marbles and which container had crayons inside (all children answered correctly). Children were then asked the following for each agent with regard to the box: "__ has never been in the room with these things before. If we show __ this box, all closed up, [picture of agent approaches the crayon box] what will __ think is inside here?'' To minimize anthropomorphic cues, half of the children were not shown a picture representing God nor were told that God had ''never been in the room''; they were simply asked, ''What will God think is inside here?'' To deemphasize Mr. Smart's visual abilities and emphasize his all-knowing capacity, children were asked what Mr. Smart would think is in the box if he stayed across the room, facing away from the box. For each agent, children earned a score of 0 if they attributed a correct belief or 1 if they attributed a false belief. Following each judgment, the interviewer prompted children to justify their answer by asking, ''Why will __ think __ are inside?''

Knowledge-ignorance understanding. To assess children's ability to distinguish knowledgeable versus ignorant agents, children were shown two boxes, each with a slit at the top allowing children to look inside. A lamp was positioned above each box. One of the lamps was turned on, illuminating the interior of the corresponding box and revealing a red plastic frog inside. The other lamp was off, and the corresponding box appeared completely empty. Children were first asked to look inside the lit box and to report what they saw. After children reported that the lit box contained a red frog, they were asked to look inside the unlit box. After children reported that they could not see anything inside the unlit box, the experimenter turned on the corresponding lamp, revealing an identical red frog inside. The latter light was then turned off, and the experimenter reminded children, ''So, both boxes have a frog inside but you can't see the frog when this one is dark'' [pointing at the unlit box]. As a memory check, children were asked whether each box, in turn, contained a frog or was empty (corrective feedback was provided for a few children as necessary). Children were then asked the following for each agent with regard to the unlit box: ''__ has never been in this room with these boxes before. If __ comes very close to the top of the dark box, what will __ think is inside here; a frog or nothing?'' For this focal question, the experimenter held the agent's picture above the unlit box, facing the contents of the box. To minimize anthropomorphic cues for half of the sample, no picture representing God was presented and children were not told that God had ''never been in this room''; they were simply asked, ''What will God think is inside here; a frog or nothing?'' while the interviewer pointed at the box. To deemphasize Mr. Smart's visual abilities, children were asked what Mr. Smart would think is in the box if he stayed across the room, facing away from the box. For each agent, children earned a score of 0 if they attributed correct knowledge or 1 if they attributed ignorance. Following each judgment, the interviewer prompted children to justify their choice by asking, ''Why will __ think a frog is inside?'' or ''Why will __ think nothing is inside?''

Results

Before conducting our focal analyses, we determined whether the presentation of an image representing God (along with language alluding to God's physical presence) was related to children's attribution of human-like (i.e., fallible or constrained) mental capacities to God. For the false-belief task, 43% of those children presented the image and language, and 36% of those who neither saw the image nor heard the language, reported that God will think crayons are in the crayon box, $\chi^2(1, 56) = 0.30$, *ns*. For the knowledge-ignorance task, 61% of children presented the image and language, and 64% of those not presented the image or language, reported that God will think nothing is inside the unlit box, $\chi^2(1, 56) = 0.08$, *ns*. Because children who were presented the ''anthropomorphic'' image and language and those not presented the image and language were equally likely to ascribe fallible capacities to God, they were combined in the focal analyses.

False-Belief Understanding

To be clear in what follows, a ''correct belief'' refers to the judgment that an agent knows what is actually in the box (its real albeit hidden contents—marbles). ''False beliefs'' refer to judgments that an agent is mistaken (i.e., will think crayons are inside the crayon box). Preliminary analyses assessed whether some children concurrently attributed human-like, false beliefs to normal humans *and* to extraordinary beings, as expected under an anthropomorphism hypothesis. Many children indeed attributed false beliefs to each of the special agents—Heroman, Mr. Smart, and God—as well as to normal humans (i.e., the girl and mom) at levels significantly different from chance (for details, see Table 1). Of primary interest was whether a pattern of attributing human-like limitations to all agents would be most common when children first began to understand that humans may hold false beliefs. We conducted an

Table 1
Chi-Square Analyses Comparing Children's Attribution of False Beliefs to Both Agents Against Chance

Agent	Heroman	Mr. Smart	God
Mother	$\chi^2(1, 18) = 8.00^{**}$	$\chi^2(1, 21) = 10.71^{**}$	$\chi^2(1, 22) = 14.73^{***}$
Girl	$\chi^2(1, 18) = 5.56^{*}$	$\chi^2(1, 21) = 8.05^{**}$	$\chi^2(1, 22) = 11.64^{***}$

Note. Eighteen children attributed a false belief to Heroman, 21 to Mr. Smart, and 22 to God.
$^{*}p < .05$. $^{**}p < .01$. $^{***}p < .001$.

exploratory analysis of children's false-belief judgments to find an age range during which children typically attributed "correct" beliefs to all agents and an immediately subsequent period during which children attributed false beliefs to ordinary humans. Based upon this exploratory analysis, we divided children into three age groups: 24 in the young group (40.4–52.4 months; *M* = 47.7), 17 in the middle group (52.5–58.9 months; *M* = 54.7), and 15 in the oldest group (59.0–73.4 months; *M* = 63.3). Figure 1 depicts the primary data: the percentage of children who attributed a false belief to each agent, by age group. Three trends are apparent in this graph: (a) with increasing age, children more often attributed false beliefs to mom and the girl; (b) children in all three age groups ascribed correct beliefs to Heroman; and (c) the youngest and oldest children attributed correct beliefs to God and Mr. Smart, whereas children in the middle age group typically attributed false beliefs to God and Mr. Smart.

Judgments. An initial repeated-measures analysis of variance (ANOVA) for children's attributions of false beliefs with age as a between-subjects factor (3: young, middle, old), and agent as a within-subjects factor (5: mom, girl, Mr. Smart, Heroman, God) revealed a significant effect for age, $F(2, 53) = 6.98$, $p < .01$, and agent $F(4, 212) = 10.50$, $p < .001$, and a significant interaction between age and agent, $F(8, 212) = 5.13$, $p < .001$. For the youngest group, there were no differences between the agents in children's attributions of false beliefs, $F(4, 92) = .57$, *ns;* children reported that all agents would think the crayon box contains marbles. On a composite measure summing responses for both the ordinary, human agents, these youngest children attributed "correct" beliefs at levels significantly above chance, $t(23) = 2.70$, $p < .05$, and did so as well on a similar measure summing responses for both Mr. Smart and God, $t(23) = 3.41$, $p < .01$. Children in the middle group attributed false beliefs to each agent (except Heroman) more often than did the youngest children, $ts(39) > 2.70$, $ps < .05$. In this group, children affirmed false beliefs at levels above chance on a composite measure of judgments for both ordinary, human agents, $t(16) = 2.70$, $p < .05$. On a parallel measure, their attributions of false beliefs for God and Mr. Smart were similar to their judgments for mom and the girl, but not significantly above chance. Note, however, that

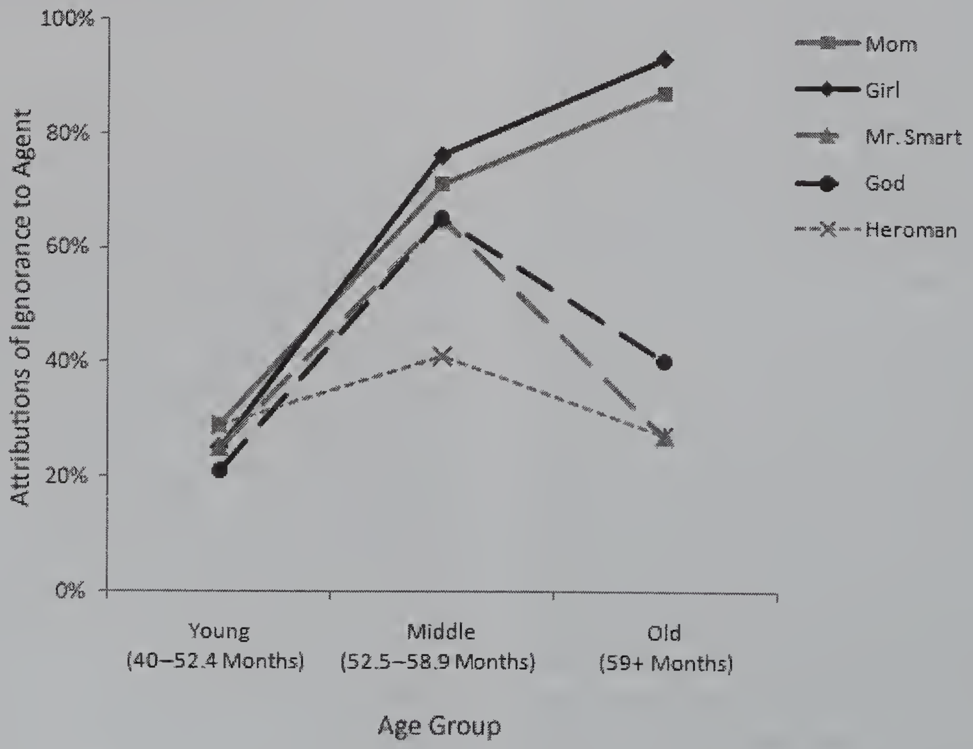

Figure 1. Percentage of children, by age group, reporting that the protagonist will hold a false belief (i.e., will think there are crayons in the crayon box).

Table 2
Coding of Open-Ended Responses

Category	Description	Examples: False-belief task	Examples: Knowledge-ignorance task
Reality based	Child cites actual contents of the containers. Child does not mention agent's mental or perceptual capacities	“There are marbles inside the box” “The crayons are in the bag” “I saw it in there”	“There is a frog inside” “I saw it in there”
Appearance based	Child cites the appearance of the box	“There are crayons on the box” “It looks like a crayon box” “It says 'crayons'”	“It's dark” “It looks like its empty”
Typicality based	Child cites the type of container or mentions what that the type of box typically holds	“It's a crayon box” “There's usually crayons in a crayon box”	“It's supposed to be in there” “Frogs live in boxes”
Exceptional perceptual capacities	Child cites agent's exceptional senses (vision, hearing) when justifying why the agent will think the true contents are inside	“He has special/x-ray/lit-up eyes” “He can see in the dark” “He heard us talking about the marbles”	“He can see in the dark” “Because he saw it” “Heard us talking about the frog”
Inadequate perceptual capacities	Child cites agent's inadequate, senses (e.g., inadequate vision)	“He can't see through things” “He can't see” “Can't see in closed things”	“It's too dark to see inside” “He can't see” “Light isn't on” [implies agent can't see]
Extraordinary mental capacities	Child cites agent's mental capacities without referring to perceptual capacities	“He's super smart” “He knows everything”	“He's very smart” “He thinks very good”
Inadequate mental capacities	Child cites agent's inadequate mental capacities without referring to perceptual capacities	“He doesn't know crayons are in there” “He doesn't know”	“He's not as smart as Smarty” “She won't know there's a frog inside'

children in this middle group *did not* grant God or Mr. Smart correct beliefs—contrary to what would be expected by a preparedness hypothesis. Only the oldest children (those 59 months and older) consistently reported that Mr. Smart and God would possess correct beliefs whereas the beliefs of mom and the girl would be false, ts(14) > 3.50, $p < .01$. Children in the middle group, as in the oldest group, affirmed correct beliefs for Heroman (tending to report that Heroman will know the crayon box actually contains marbles) in contrast to the false beliefs of mom, $t(16) > 2.06$, $p < .06$, and the girl, $t(16) > 2.40$, $p < .05$.

Justifications. Children's justifications help clarify the reasoning behind their judgments. Children's justifications were coded into seven categories, as outlined in Table 2, and a residual uncodable category (“don't know”). Twenty percent of the justifications were coded by two separate coders (one blind to all hypotheses and aims of the study) to assess interrater reliability (all κs ≥ .96). We focus on three contrasting agents: Heroman (whose special vision was described), Mr. Smart (who was described as having an extraordinary mind, but no specific exceptional perceptual mechanism), and God (about whom we told children nothing). Table 3 presents data on the primary forms of reasoning that children used to justify these three agents' correct beliefs. Justifications for correct beliefs are particularly revealing because they address which (if any) extraordinary capacities children attributed to these agents.

The youngest children generally did not appreciate these agents' mental capacities or knowledge-collecting mechanisms; rather, they evidenced a reality bias (or said something uninformative). Most of the youngest children said that Heroman would know that the box contains marbles, but fewer than a third referred to his exceptional vision (e.g., “He has super eyes”). Rather, most of these

Table 3
Justifications for Attributions of Correct Beliefs and Knowledge

		Correct belief reasoning				Correct knowledge reasoning			
Age group	Agent	Reality based	Exceptional perceptual capacities	Extraordin. mental capacities	Uninformative	Reality based	Exceptional perceptual capacities	Extraordin. mental capacities	Uninformative
Young	Heroman	24%	29%	6%	35%	29%	14%	14%	43%
	Mr. Smart	17%	6%	28%	33%	13%	—	13%	50%
	God	32%	5%	5%	37%	17%	—	17%	50%
Middle	Heroman	10%	60%	10%	—	18%	73%	—	—
	Mr. Smart	17%	—	67%	17%	33%	—	67%	—
	God	50%	17%	17%	—	67%	—	—	33%
Oldest	Heroman	—	100%	—	—	33%	67%	—	—
	Mr. Smart	—	—	100%	—	35%	5%	60%	—
	God	—	22%	56%	—	42%	25%	17%	17%

Note. Age ranges for the false-belief task are: young (40.4–52.4 months), middle (52.5–58.9 months), and oldest (59.0–73.4 months). Age ranges for the knowledge-ignorance task are: young (40.4–49.4 months), middle (49.5–54.5 months), and oldest (54.6–73.4 months). Extraordin. mental capacities = extraordinary mental capacities.

children justified Heroman's correct beliefs by citing reality (e.g., "There is crayons inside"), confabulating a reason (e.g., "He guessed"), or provided an uninformative response (e.g., "Because" or "I don't know"). In this young group, of the children who said that Mr. Smart or God would think that the crayon box contains marbles (correct belief), only a few provided justifications indicating an appreciation for Mr. Smart's or God's extraordinary mental capacities (e.g., "He's super smart"). Of the remaining children who attributed correct beliefs to Mr. Smart and God, most justified these agents' correct beliefs by citing reality or provided an uninformative response. In sum, when attributing correct beliefs to these special agents (as was typical for these young children, who generally attributed correct beliefs to *all* agents), only 22% of children's responses mentioned anything like exceptional perception or extraordinary mental capacities, although such special capacities were described to children at several points in our protocol.

In the middle group, most children attributed a correct belief to Heroman, and more than half justified their answers by specifically referring to Heroman's extraordinary vision (e.g., "He can look through things"). However, most children attributed to all other agents a false belief. Of the 11 children who attributed a false belief to Mr. Smart, 10 (91%) cited the appearance of the box (e.g., "There's a picture of crayons on the box") or the type of box (e.g., "It's a crayon box"). Similarly, of the 11 children who attributed a false belief to God, 9 (82%) cited the appearance of the box or the type of box. When attributing correct beliefs to these special agents, children in this middle group cited exceptional perception or extraordinary mental capacities in 55% of their responses.

Just as in their judgments, the oldest children's justifications suggested an appreciation for Heroman's perceptual prowess *and* for Mr. Smart's and God's extraordinary minds. All children in the oldest group who attributed a correct belief to Heroman cited his extraordinary vision, and every child who attributed a correct belief to Mr. Smart cited his mental capacities (e.g., "He's so smart"). Interestingly, of the children who attributed a correct belief to God, about half cited extraordinary mental capacities (e.g., "He knows everything"), but several attributed to God exceptional visual capacities (e.g., "He can see through anything"). Overall, when attributing correct beliefs to these special agents (the typical response for the oldest children), older children appealed to exceptional perception or extraordinary mental capacities 94% of the time. In sum, when attributing correct ("infallible") beliefs to these agents, young children rarely referred to agents' extraordinary perceptual or mental capacities; however, this sort of reasoning was provided often by the middle age group and especially by the oldest children.

Knowledge-Ignorance Understanding

With regard to children's understanding of agents' ignorance, we again first determined whether some children concurrently attributed human-like, constrained capacities to most agents. For clarification, we use the phrase ''correct knowledge'' when referring to children's judgments that the agent knows what is actually in the box (its real but hidden contents—a frog). ''Ignorance'' refers to children's judgments that the agent is mistaken (i.e., will think the box is empty). A significant number of children attributed ignorance to each of the special agents—Heroman, the cat, Mr. Smart, and God—as well as to the ordinary humans (i.e., the girl and mom), at levels significantly different from chance (see Table 4 for details). Again, of primary interest was whether this pattern would be most common among children who were just beginning to understand that ordinary humans' knowledge can be limited by perceptual access. We conducted an exploratory analysis of children's knowledge-ignorance judgments to find an age range when children typically attributed ''correct'' knowledge to all agents, and a subsequent period when children attributed ignorance to ordinary humans. Based on these preliminary analyses, we divided children into three age groups. Because children evidenced an understanding of ignorance at an average age of 4 months younger than an understanding of false beliefs, for knowledge-ignorance analyses there were 12 children in the young group (40.4–49.4 months; *M* = 44.2), 20 in the middle group (49.5–54.5 months; *M* = 52.2), and 24 in the oldest group (54.6–73.4 months; *M* = 60.5). Figure 2 depicts the focal data: the percentage of children who attributed ignorance to each agent, per age group. Three trends are noticeable in this graph: (a) with increasing age, children more often attributed ignorance to mom and the girl, with a later leveling off; (b) children in all three age groups attributed correct knowledge to Heroman

Table 4
Chi-Square Analyses Comparing Children's Attribution of Ignorance to Both Agents Against Chance

Agent	Cat	Heroman	Mr. Smart	God
Mother	$\chi^2(1, 14) = 4.57^*$	$\chi^2(1, 20) = 7.20^{**}$	$\chi^2(1, 22) = 6.55^*$	$\chi^2(1, 35) = 17.86^{***}$
Girl	$\chi^2(1, 14) = 7.14^{**}$	$\chi^2(1, 20) = 12.80^{***}$	$\chi^2(1, 22) = 18.18^{***}$	$\chi^2(1, 35) = 27.46^{***}$

Note. Fourteen children attributed ignorance to the cat, 20 to Heroman, 22 to Mr. Smart, and 35 to God.
$^*p < .05$. $^{**}p < .01$. $^{***}p < .001$.

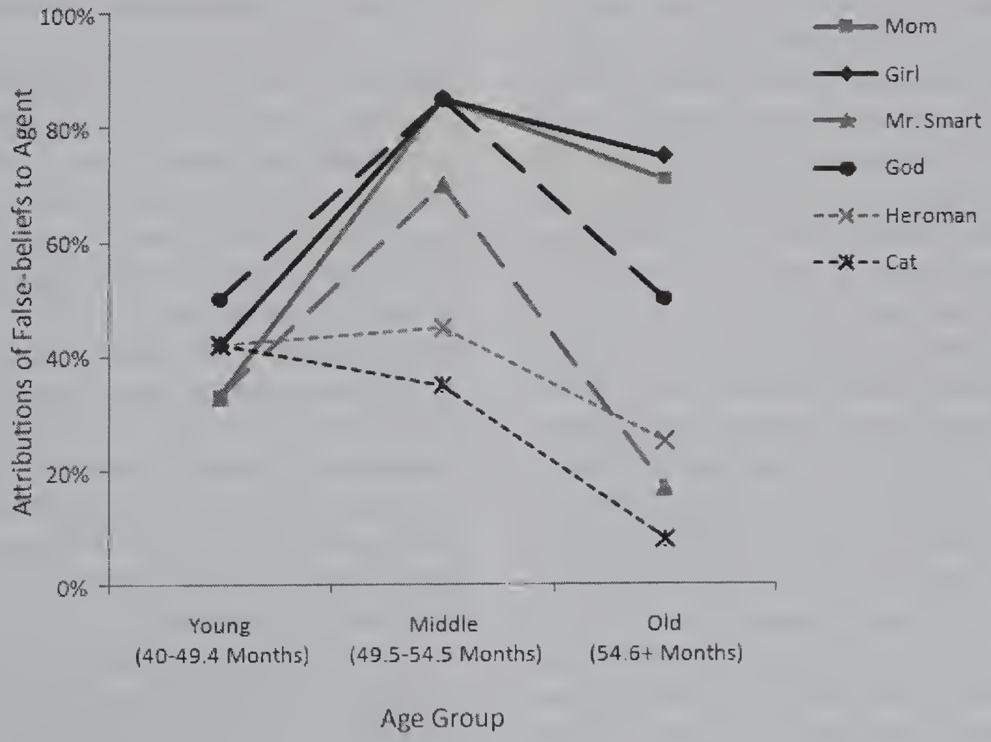

Figure 2. Percentage of children, by age group, reporting that the protagonist will not perceive the contents of the unlit box (i.e., will think that the unlit box is empty).

and the cat, a tendency that was particularly pronounced in the oldest age group; and (c) children in the young and old age groups attributed correct knowledge to God and Mr. Smart, whereas children in the middle age group attributed ignorance to God and Mr. Smart.

Judgments. A repeated measures ANOVA for children's attributions of ignorance with age as a between-subjects factor (3: young, middle, old) and agent as a within-subjects factor (6: mom, girl, Mr. Smart, Heroman, God, cat), revealed a significant effect for age, $F(2, 53) = 4.73$, $p < .05$; agent, $F(5, 265) = 11.16$, $p < .001$; and an interaction between age and agent, $F(10, 265) = 3.58$, $p < .001$. For the youngest children, there were no differences in children's attribution of ignorance between the agents, $F(5, 55) = .61$, *ns*, and they attributed ignorance to all agents at chance levels. Children in the middle group attributed ignorance to agents (except Heroman and the cat) more often than did the youngest children, $ts(30) > 2.09$, $ps < .05$. They did so above chance on a composite measure of judgments for both ordinary, human agents, $t(19) = 6.66$, $p < .001$, and notably were above chance on a similar composite measure for both Mr. Smart and God, $t(19) = 3.24$, $p < .01$. These children (along with the oldest children) distinguished between the correct knowledge of Heroman and the cat and the ignorance of mom and the girl, $ts(19) > 2.99$, $ps < .01$. Notably, in the middle age group, only the two agents who were specified as possessing exceptional vision were judged to know the correct contents of the dark box; God and Mr. Smart were judged to be ignorant. Only the oldest group of children (54 months and older) consistently reported that whereas mom and the girl would think the unlit box is empty, Mr. Smart and God would have correct knowledge that the unlit box contains a frog, all $ts(23) > 2.77$, $ps \leq .01$, except for the difference between mom and God, which was marginally significant at $p < .06$.

Justifications. Children's justifications shed light on the reasoning behind their judgments. Justifications were coded into the same seven focal categories as before (see Table 2). Twenty percent of the justifications were coded by two coders (one unaware of the hypotheses and aims of the study) to assess interrater reliability (all $\kappa s \geq .88$). We focus on four contrasting agents: Heroman and the cat (whose exceptional visual abilities were described), Mr. Smart (whose extraordinary mind was described but who was not given a special perceptual mechanism), and God (about whom we told children nothing). Table 3 presents data on the most common forms of reasoning that children used to justify Heroman's, Mr. Smart's, and God's correct knowledge.

For the youngest children, most judged that Heroman and the cat would know that the box contains a frog, but only 1 of these children for each agent referred to special vision ("He can use his light sensy" and "He can see in the dark"). In contrast, most of these children justified these agents' correct knowledge by citing reality (e.g., "I saw a frog") or provided an uninformative response (e.g., "Because" or "I don't know"). In this young group, of the many children who reported that Mr. Smart would know that the unlit box contains a frog, only 1 provided a justification that suggested he appreciated Mr. Smart's extraordinary mind ("He knows everything"), and only 1 of the children who reported that God would know that the box contains a frog cited God's mental capacities ("He knows everything at church"). The remaining children justified Mr. Smart's and God's correct knowledge by citing the real nature of the box, or provided uninformative responses. In summary, when attributing correct knowledge to these special agents (the typical response for the young children, who generally attributed correct knowledge to *all* agents), in only 21% of their responses did the youngest children appeal to exceptional perception or extraordinary mental capacities.

In the middle group, most judged Heroman and the cat to have correct knowledge. Almost all these children provided justifications that specifically referred to these agents' exceptional vision (e.g., "He can see through anything" and "He can see in the dark," respectively). Most children attributed to all other agents ignorance. Of the 14 children who attributed ignorance to Mr. Smart, 4 (29%) justified their responses by citing the appearance of the box (e.g., "It's dark") and 7 (50%) referred to Mr. Smart's inadequate visual capacities (e.g., "It's hard to see"). Similarly, of the 17 children who attributed ignorance to God, 3 (18%) referred to the appearance of the box (e.g., "It's dark") and 10 (59%) justified their responses by referring to God's inadequate visual capacities (e.g., "He can't see in the dark"). When attributing correct beliefs to these four special agents, children referred to exceptional visual capacities or extraordinary mental abilities in 73% of their responses.

The oldest children's justifications suggested a greater appreciation for Mr. Smart's and God's extraordinary mental capacities, in addition to an appreciation for Heroman's and the cat's exceptional vision. Most of the oldest children judged Heroman and the cat to have correct knowledge, and a majority of these children justified their judgments by explicitly referring to these agents' exceptional visual capacities. Of the children in this group who attributed correct knowledge to Mr. Smart, more than half cited his extraordinary mental capacities (e.g., ''He knows everything''), 1 referred to exceptional visual capacities (''He can see anything''), and a third cited reality. Of the children who attributed correct knowledge to God, almost half cited reality, whereas others cited extraordinary mental capacities (e.g., ''He knows everything'') or exceptional visual capacities. In short, when attributing correct knowledge to these four agents (the typical response for the oldest children), the oldest children cited exceptional perception or extraordinary mental abilities in 63% of their responses.

Discussion

Not only do children everywhere come to understand the basic mental and perceptual capacities of ordinary human agents, they come to entertain ideas about agents with extraordinary capacities, including religious deities. Recent research on children's understanding of extraordinary, nonhuman minds has been aimed at comparing and contrasting two opposing positions: the anthropomorphism hypothesis and the preparedness hypothesis. From the *anthropomorphism* perspective, very young children initially understand all intentional agents as possessing human-like capacities. Three-year-olds fall prey to a reality bias—they do not consider agents' mental abilities and thus fail to distinguish between the state of reality and people's (often inaccurate) mental states. As children begin to appreciate that humans' capacities are limited and fallible, they initially attribute similar limitations to all agents. After developing an understanding of ordinary, human capacities, children can appreciate that certain agents may conceivably have exceptional or extraordinary powers. Thus, to understand extraordinary agents' special capacities, children must overcome or modify their intuitive conceptions of agents and increasingly think in counterintuitive, nonanthropomorphic terms. The alternative *preparedness* perspective proposes that very young children begin life well equipped to understand that certain agents possess nonhuman capacities (e.g., infallible beliefs) because they have an initial ''default assumption'' that ''many superhuman properties are the norm'' (Richert & Barrett, 2005, p. 284). Because initially all beliefs are true and all agents infallible, for special agents (God or others when they are explicitly told the agent has superhuman capacities or states) children need merely and easily continue to see them as superhuman.

A crucial developmental difference exists for these two positions. According to the anthropomorphism hypothesis, there should exist a developmental point, once children begin to attribute fallible capacities and states to humans, when they attribute these states to all agents, even agents adults contend are infallible (e.g., God) and children have heard are infallible (perhaps God, but in our tasks explicitly Mr. Smart). For the preparedness hypothesis, on the other hand, because superhuman properties are the default ''norm,'' children need not struggle to reason counterintuitively about such agents and, as a consequence, there should be no developmental point when these agents are attributed fallible, limited capacities or states. For both positions, an intriguing contrast case concerns agents with more limited extension of ordinary capacities, such as night vision or X-ray vision.

In accordance with the anthropomorphism hypothesis, we found that children reliably attributed ordinary, human-like capacities to special agents for both a false-belief task and a knowledge-ignorance task. Children not only did this for God but also did so for agents whose extraordinary mental capacities and exceptional perceptual mechanisms were explicitly described and demonstrated to them. Normatively, children come to understand ignorance before understanding false beliefs; this is true in precise scaling comparisons (e.g., Wellman & Liu, 2004) and is apparent in our own data as well. Accordingly, we found that the age-related developmental period during which children were especially likely to consider most agents' capacities to be human-like differed between these two forms of mental understanding, a sequential pattern that seems to accord more with an anthropomorphism position. A prepared, early understanding of infallibility should generally apply to knowledge and belief; overcoming an early reality bias could more sensibly apply first to developmentally ''easier'' mental states (ignorance), then more complicated mental states (false beliefs). Thus, it is of note that our data show that these children came to understand the ordinary limits of one and then another mental capacity, and subsequently entertained the counterintuitive suspension of those limits in sequence.

In apparently contradicting the results and conclusions of Barrett and colleagues, the current findings join two other recent studies. Using a different type of knowledge-ignorance task with Greek Orthodox children, Makris and Pnevmatikos (2007) found that 3- and 4-year-olds held that God and a little girl would *both not know* the contents of a closed box. Only at age 5 did participants differentiate between the girl's ignorance and God's correct knowledge of the box's true contents. Similarly, using modified knowledge-ignorance and false-belief tasks with a sample of Spanish children, Giménez-Dasí et al. (2005) found that, compared with 3- and 5-year-olds, their 4-year-olds more often attributed ignorance and false beliefs to God, and this was the case for children who were attending religious as well as those attending nonreligious preschools.

Our data go beyond other results, however, in clarifying how the overall pattern of apparently contradictory findings could arise depending on the way in which children were sampled and grouped. That is, our finding of specific ''anthropomorphic'' developmental periods (using tasks similar to those used by Barrett et al., 2001) was a product of careful age sampling and precise age-related analyses of the data. Suppose instead we reexamine our data after removing participants to correct for our dense sampling in the middle age range and simply divide our remaining children into three arbitrary age groups. Then only two age-graded linear trends emerge: (a) an increasing tendency to attribute fallible capacities to the girl and mom and (b) a constant trend to attribute ''infallible'' capacities to God, Mr. Smart, and Heroman. That is, with less precise sampling and age grouping, our data would mimic the trend lines shown in Barrett's work (e.g., Barrett et al., 2001; Knight et al., 2004). But as is clear in Figures 1 and 2, such analyses would actually mask three different trends: (a) an increasing linear trend to attribute fallible mental states to the girl and mom, (b) an apparently constant trend to attribute correct mental states to the cat and Heroman, and (c) a curvilinear trend where, with age, children first increasingly attribute fallible mental states to Mr. Smart and God, and only later attribute extraordinary, correct mental states to those superhuman agents. The latter trend thus parallels the findings of Makris and Pnevmatikos (2007), and also of Giménez-Dasí et al. (2005), and suggest that their data, too, may have emerged from samples and groupings that were able, like our own, to reveal more precise and detailed developmental trends.

Crucially, earlier studies provide limited information on what specific capacities children are attributing to extraordinary agents. The exception is Giménez-Dasí et al.'s (2005) finding that, when asked, 4- and 5-year-olds often justified their answers that God's knowledge was limited by referencing God's limited perceptual capacities. In our more comprehensive assessment of children's reasoning, we distinguished children's appreciation for mental capacities (e.g., infallible beliefs) from their appreciation for perceptual capacities (e.g., night vision). We used two techniques to provide this additional, needed, information: (a) asking children about the knowledge and beliefs of agents with contrasting mental and perceptual capacities and (b) asking children to explain their responses. These techniques jointly revealed that children in the middle age groups appreciated that most humans (such as the girl, mom, and Mr. Smart) as well as God have constrained access to certain information. However, they also reasoned that other agents who possess specific perceptual mechanisms to access information (such as the exceptional visual capacities of the cat and Heroman) may gain knowledge that would be elusive to most humans. It is conceivable that children attributed accurate knowledge and beliefs to Heroman merely because he held ''superhero'' status, and thus they understood him as being *all-capable* within a pretend world. However, on the knowledge-ignorance task, children treated Heroman just as they treated the cat—an agent who was not presented as a ''super'' agent. Moreover, for both tasks, children who attributed accurate knowledge and beliefs to Heroman justified their judgments by specifically referring to his *visual* abilities and not to his other exceptional abilities, such as his ability to fly fast.

Only the oldest children appreciated Mr. Smart's and God's extraordinary mental capacities in the absence of exceptional perceptual mechanisms through which knowledge or beliefs could be acquired—Mr. Smart was described as being very smart and knowing everything, but we did not tell children how he acquired information other than saying that it was not based on vision. These data thus provide converging evidence that contradict the preparedness hypothesis, which specifically describes superhuman capacities, such as infallible beliefs, as the default. According to the preparedness hypothesis, children should have simply continued with this default position when taught about Mr. Smart, but they did not. Similarly, only the oldest children understood the extraordinary mind of God, about whom we provided no background information. Perhaps, in comparison with religiously trained children, the children in our sample lacked knowledge of God's powers, and this is the reason why children in the middle age group tended to anthropomorphize God—they simply had not learned about God's powers. Following the interview, we did ask children what they know about God. Exploratory analyses did not indicate that there were differences in the responses of children based upon their knowledge of God. The children who could provide details about God, for example, were evenly distributed between the three age groups for the knowledge-ignorance task—about a third (35%) were in the middle ''anthropomorphic'' age group—and these children comprised about half (45%) of the children in the middle age group. Moreover, we found the same trends for God as we did for Mr. Smart, an agent about whom children definitely had relevant background information. However, our measures did not sensitively capture details of children's prior religious instruction, and our parental reports of children's religious exposure were available for only 39 of 56 children. It is important that future research be conducted using similar methods to assess these developing concepts in children who are exposed heavily to theistic ideas.

Although the current results go a long way toward clarifying children's developing ideas about extraordinary minds and exceptional perceptual capacities, they also raise several questions that could be addressed with future research. First, although we found that a substantial portion of children attributed fallible capacities to the two agents described as having exceptional perceptual capacities—Heroman and the cat—we did not find a specific developmental period during which children were particularly likely to anthropomorphize these agents. It is possible that an even finer-grained age sampling and analysis might uncover earlier anthropomorphic windows for children's understanding of exceptional perceptual capacities. Second, our findings do *not* indicate that our oldest children were attributing *omniscience* to Mr. Smart and God, although some researchers have used that term when interpreting their data (e.g., Giménez-Dasí et al., 2005; Knight et al., 2004). Understanding omniscience requires that one appreciates that an agent not only knows the contents of closed containers but also truly knows *everything*—the nature of all past and future events, all scientific facts, everyone's unspoken intentions and dreams, and so on. Rather, our oldest children likely understood God's and Mr. Smart's powers in a much less counterintuitive manner—Mr. Smart and God think like humans, but they know more (about certain tangible things in the here and now) than normal humans. It would certainly be interesting in future studies to address how children come to entertain increasingly counterintuitive concepts of extraordinary mental capacities and how this might eventually lead to a sophisticated understanding of omniscience.

In summary, our data lend critical support to the anthropomorphism hypothesis while also suggesting ways in which this hypothesis might be modified. When these children first began to overcome their initial reality bias and started to understand the limits of human mental capacities (e.g., that ordinary humans possess ignorance and false beliefs), they applied this same understanding to God and to an agent who was described as possessing extraordinary mental capacities. Meanwhile, during this ''anthropomorphic'' period, children appreciated that knowledge and beliefs may be acquired via highly specialized, nonhuman perceptual capacities—such as eyes that see in the dark. This initial grasp of exceptional perceptual capacities may well act as a bridge to a later understanding of even more counterintuitive, superhuman capacities. By age 5, children understood that agents with special mental capacities, such as the ability to know everything, may possess knowledge and beliefs without necessarily relying on specialized perceptual mechanisms for acquiring that information. Such early abilities to understand extraordinary capacities are indeed impressive. These abilities allow children to begin to grasp religious teachings that are seemingly counterintuitive, such as God's omniscience. But, importantly, this early understanding of the extraordinary is built upon an earlier and more fundamental understanding of the ordinary.

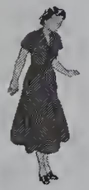
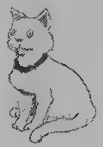
Girl

Let's talk about Mary. [Show picture of Mary]



Mom

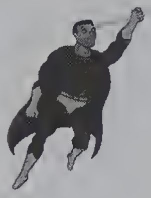
Let's talk about your mom. [Show picture of mom] It's not really a picture of your mom, but let's say it is.



Cat

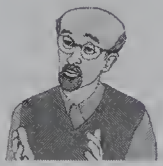
This is a kitty cat. [Show picture of cat] This kitty cat has special eyes that let him see in the dark.

Appendix
(*Continued*)



Heroman

[Show picture of Heroman and say:]
This is Heroman. Heroman has super powers. He can fly very fast so that he can help lots of people all over the world. He *also has eyes* that let him see the insides of things, he can even see through walls.
[Show child a pen] Can you see this pen? [Place pen out-of-sight, behind paper]
Now can you see the pen? [Place picture of Heroman on child's side of the paper]
Well, Heroman can still see the pen. He can see through the paper and see the pen on the other side.
Remember, Heroman can fly very fast and can see right through things.



Mr. Smart

[Show picture of Mr. Smart, facing the child (away from the box) and say:]
This is Mr. Smart. Mr. Smart has special powers. He knows everything.
[Show child closed opaque container that has a ball inside]
Do you know what's inside here? [Child responds: ''No'']
Well, this is the first time that I've played with this, so I don't know what's inside either. Mr. Smart *also* hasn't played with this before. But because he's so smart he still knows what's inside. We would have to look inside, but he wouldn't even need to look.
Mr. Smart, what do you think is in here? [Lean next to Mr. Smart]
Mr. Smart thinks that there is a ball inside. Let's see. [Open container and show child the ball]
Mr. Smart was right! Wow, he knows everything!
Remember, Mr. Smart is very smart. He knows everything.
[Place Mr. Smart face-down, away from box]

God

Let's talk about God. [Show picture] It's not really a picture of God, but let's say it is.

Note. Picture representing God (and language alluding to God's physical presence) was only presented to half of the sample.

Maternal Discussions of Mental States and Behaviors: Relations to Emotion Situation Knowledge in European American and Immigrant Chinese Children

Stacey N. Doan and Qi Wang
Cornell University

This study examined in a cross-cultural context mothers' discussions of mental states and external behaviors in a story-telling task with their 3-year-old children and the relations of such discussions to children's emotion situation knowledge (ESK). The participants were 71 European American and 60 Chinese immigrant mother–child pairs in the United States. Mothers and children read a storybook together at home, and children's ESK was assessed. Results showed that European American mothers made more references to thoughts and emotions during storytelling than did Chinese mothers, who commented more frequently on behaviors. Regardless of culture, mothers' use of mental states language predicted children's ESK, whereas their references to behaviors were negatively related to children's ESK. Finally, mothers' emphasis on mental states over behaviors partially mediated cultural effects on children's ESK.

Children's understanding of emotions has emerged as an important foundation for a range of adaptive behaviors related to social competence and school readiness (Denham, 2006; Izard et al., 2001). The development of the abilities to grasp the causes and consequences of one's own as well as others' emotions begins early. Children start to use basic emotional terms at about 20 months (Bretherton, McNew, & Beeghly-Smith, 1981) and are able to match emotional terms with facial expressions at age 2 (Russell & Bullock, 1986). During the preschool years, children come to be increasingly adept at understanding the situational antecedents of feeling states and can identify individual emotions and the situations that provoke them (Denham, 1986; Dunn, Brown, Slomkowski, Tesla, & Youngblade, 1991; Harris, Olthof, Terwogt, & Hardman, 1987). Furthermore, preschoolers have come to understand how perception, desire, and emotion are related in a causal way (Wellman, Phillips, & Rodriguez, 2000), and how thinking about past situations can influence current emotions (Lagattuta & Wellman, 2001).

A burgeoning field of research has focused on early socialization as playing a critical role in children's developing emotional understanding (Denham, 1993; Dunn, Bretherton, & Munn, 1987; Dunn, Brown, & Beardsall, 1991; Eisenberg, Cumberland, & Spinrad, 1998). Specifically, parent–child conversations about emotions and mental states have been shown to be pivotal in predicting children's later understanding of emotion (Dunn, Brown, & Beardsall, 1991; Taumoepeau & Ruffman, 2006, 2008). Most of these studies, however, have focused on children of European descent. Less is known about the socialization of emotional understanding in different cultural contexts and its implications for developmental outcomes. In this study, we examined early narrative practices in European American and Chinese immigrant families in the United States and the impact of these practices on children's developing emotion situation knowledge (ESK).

Socialization of Emotional Understanding

In general, collaborative conversations rich in mentalistic terms with adults, peers, and siblings

may aid children's social-cognitive development in various ways. Naming psychological states makes the states explicit, which draws attention to and encourages reflection on these states (Dunn, Brown, Slomkowski, et al., 1991; Ornstein, Haden, & Hedrick, 2004; Wellman, Harris, Banerjee, & Sinclair, 1995). Furthermore, during such conversations children are often exposed to the possibility of differing perspectives and conflicting emotions between the self and others, which may further facilitate their perspective taking and emotional understanding (Harris, 1999).

In line with these theoretical proposals, longitudinal research has shown that early exposures to discussions of mental states contribute to children's emotional understanding (Dunn, Brown, & Beardsall, 1991; Taumoepeau & Ruffman, 2006, 2008). Furthermore, Meins and her colleagues have identified maternal mind-mindedness as a particular type of interaction style that seems to be an important mechanism underlying children's development of complex social cognitive abilities (Meins & Fernyhough, 1999; Meins et al., 2002; Meins et al., 2003). Mothers who are high on mind-mindedness treat their children as autonomous, independent individuals with desires, feelings, and thoughts. During conversations, they pay great attention to their children's mental attributes as opposed to physical appearance or behavioral tendencies. Although mind-mindedness was originally conceptualized as having both behavioral (e.g., looking at the object at which the infant's gaze was directed) and linguistic components (e.g., appropriate references to mental states), further research has shown that the specific aspect of mind-mindedness that appears to facilitate children's social-emotional understanding is the frequency with which mothers refer to mental states, desires, and emotions (Ruffman, Slade, & Crowe, 2002; Taumoepeau & Ruffman, 2006, 2008).

A study by Taumoepeau and Ruffman (2006) provided further evidence for the effects of maternal usage of mental states language on children's emotional understanding. In this study, mothers were asked to describe picture books to their children when children were 15 and 24 months old. Children's emotional understanding was assessed at the second time point by their ability to match emotional faces with a variety of affect-eliciting situations (e.g., a boy being chased by a lion) and by their ability to determine how a person was feeling by their body position. Mothers' references to desires predicted children's later usage of mental state terms, as well as children's emotional understanding. These effects were independent of children's language skills, family socioeconomic status (SES), and mothers' performance on an emotion recognition task. In a follow-up study (Taumoepeau & Ruffman, 2008), the researchers visited the children at 33 months and found that mothers' references to thoughts and knowledge were a more consistent predictor of children's emotional understanding at this later age. The researchers suggest that mothers scaffold children's understanding of mind through their use of specific mental state terms, starting first with desires and progressing to cognitions when children's understanding of mental states are more nuanced.

Thus, family discussions of mental states appear to play an important role in the socialization of emotional understanding. Notably, however, this suite of research has mainly focused on children and families of European descent. At its core, mental states language conveys individual realities and experiences to others, with the emphasis being placed on the internal (e.g., the psychological states of the individual) as opposed to the external (e.g., social and contextual factors). Such an emphasis may be further related to the Western cultural value of individualism, autonomy, and independence. Despite research documenting divergent cultural value systems (Greenfield, Keller, Fuligni, & Maynard, 2003; Kagitcibasi, 2005; Markus & Kitayama, 1991) and their effects on communication styles and preferences (Kim, 2002), there is no study to date that directly examines family discussions of mental states in different cultural contexts and their consequences for children's emotional understanding.

Early Narrative Practices in Cultural Contexts

Narrative practices may reflect the theory of language upheld in a culture (Hansen, 1983, 1989). In Western cultures, language often maps onto ''belief psychology,'' with the function of language being descriptive or representative. In this context, the communicative use of language tends to convey meaning, including ideas, thoughts, and concepts. This is in contrast to traditional Chinese culture where the use of language often serves a regulative function in guiding behavior and coordinating social interactions. As Hansen (1983, p. 61) claims, in the Chinese context ''the function of words is to engender and express attitudes with implications for action rather than to express some 'content' such as the speaker's thoughts.'' Consistent with this view, recent research examining the way in which mothers communicate with their children has found that during personal storytelling, European American parents more frequently encourage children to describe their thoughts, preferences, wishes, and perceptions than Japanese, Korean, and Chinese parents, who are more didactic, focusing on children's behaviors and moral obligations (Martini, 1998; Wang, 2001; Wang, Leichtman, & Davies, 2000).

Particularly relevant to the current research, Wang et al. (2000) found that compared with Chinese mothers, European American mothers often made more comments on mental states and were more likely to refer to the child's personal needs, preferences, judgments, and opinions when sharing memories and telling stories. These cultural differences in mother–child conversations appear to play out even when the subject under discussion is emotional. For example, Fivush and Wang (2005) examined Chinese and European American mothers' conversations about positive and negative emotionally salient events (e.g., birthday parties, conflict with parents or peers). They found that although the sheer volume of conversations did not differ between cultures, American mothers provided more causal explanations for both their children's and others' emotions than did Chinese mothers, who tended to emphasize social norms and behavioral expectations when discussing emotions with their children.

These different beliefs and practices pertaining to the functions of language in communicative contexts are further echoed in the value systems across cultures. In European American culture where a great emphasis is placed on individuality and agency, individuals are encouraged to express their thoughts, ideas, and emotions, which, in turn, help to affirm their autonomous sense of self. In contrast, Chinese culture prizes group harmony and interrelatedness; emphasis is placed on an individuals' overt behavior and its regulation because it may have direct consequences on group functioning. Individuals' thoughts and emotions, in this context, are often deemphasized as they may be socially divisive (Markus & Kitayama, 1991). Indeed, research has shown that East Asian adults and children rely more on behavior-descriptive verbs in person descriptions than their Western counterparts, who tend to prefer trait adjectives (Maas, Kurasawa, Politi, & Suga, 2006; Wang, 2004). East Asian children have been shown to justify another person's false beliefs by overt behaviors and social rules rather than mental states (Naito & Koyama, 2006). Furthermore, Chinese parents tend to view their children's behavior as highly malleable rather than genetically determined, which leads to their emphasis on focusing and regulating behaviors in the child (Stevenson, Chen, & Lee, 1993).

The cultural difference in emphasizing mental states versus external behaviors may have important consequences for children's developing emotional understanding. When asked to judge the emotional nature of story situations or to describe situations likely to provoke various emotions, European American preschoolers scored higher than their Chinese peers regardless of age, and they made more rapid progress in ESK over time (Wang, 2003; Wang, Hutt, Kulkofsky, McDermott, & Wei, 2006). Conceivably, the emphasis on mental states and affect in early narrative practices in European American families may have facilitated European American children's emotional understanding. Nonetheless, there has been no direct evidence concerning the influence of maternal references to mental states on children's developing emotional understanding across cultures. Also, no cross-cultural data are available about family discussions of external behaviors and how they may be related to children's emotional understanding. Conceivably, a focus on external behaviors may draw children's attention outward and render inner psychological states less salient. As a result, it may hinder the development of emotional understanding.

Purposes of the Current Study

The purpose of this study is threefold. First, we examine references to mental states and overt behaviors during mother–child storytelling in European American and Chinese immigrant families. Second, we examine the relation of mental states and behavioral references to children's emotional understanding. We focus on children's understanding of situations that elicit specific emotions, namely, ESK (Denham, Zoller, Couchoud, & Holt, 1990; Harris et al., 1987). This aspect of emotional understanding may be critical for the actual emotional experience within event situations (Fridja, 2008) and may play an important role in affecting how children understand and represent significant personal experiences (Wang, 2008). Furthermore, the ability to understand how situational cues can be used to infer others' emotions is crucial for children's navigation of social relationships and their social-emotional well-being (Fine et al., 2003; Izard et al., 2001).

Finally, we test a mediation model examining whether the emphasis on mental states rather than behaviors during mother–child storytelling mediates cultural influences on children's ESK. We hypothesized that during storytelling, Chinese mothers would make more references to behaviors than European American mothers, who would make more references to mental states. And consistent with previous findings (Wang, 2003; Wang et al., 2006), European American children would score higher on ESK than Chinese children. Furthermore, maternal emphasis on mental states relative to behaviors in conversations would have a facilitative effect on children's ESK, regardless of culture. Finally, we hypothesized that mental states language would serve as an important mediator that gave rise to cultural differences in children's ESK.

Method

Participants

The participants were 60 Chinese immigrant (30 boys; age range = 30–43 months, $M = 35.00$ months) and 71 European American (37 boys; age range = 30–42 months, $M = 35.49$ months) children and their mothers from a university town and suburban areas in upstate New York. The mean age was not significantly different across the two cultures. Children were recruited through local schools and by word of mouth, and were taking part in a larger longitudinal study of sociocognitive development across the preschool years. All children came from middle-class backgrounds, with the majority of the mothers (Chinese immigrant, 98%; European American, 93%) having obtained a college degree or beyond. Chinese immigrant families were originally from mainland China, Hong Kong, and Taiwan, with the majority from mainland China (93%). Most (80%) of the children were born in the United States.

Procedure

Two female researchers visited mothers and children in their homes. Chinese-English bilingual researchers visited the Chinese immigrant families. Of the 60 Chinese immigrant children, 80% spoke only Chinese and the rest spoke English or a mixture of English and Chinese. Before commencing with children's interviews, the researchers established familiarity and rapport with the children by chatting about nonrelevant events. All materials were written in both English and Chinese and a translation and back-translation procedure was carried out to ensure their equivalence in both literal and sense meaning. Mothers were asked to engage the child in a series of free play and semistructured tasks, followed by a researcher–child session. The entire home visit took approximately 1½ hr and was video tape-recorded. Only the tasks relevant to the current study are described here.

Measures

Mother–child storytelling. Mothers' use of mental states language and references to behaviors were assessed in a storytelling task. Joint picture book reading has been found to be a common practice among middle-class families in both European American and Chinese cultures (Johnston & Wong, 2002; Li, 2006). Mothers received a book entitled *Bear Goes to the Market*, a children's book with illustrations but no words. The storybook is 17 pages long and contains culturally neutral themes. It has been developed for and has been used in previous cross-cultural research with European American and Chinese samples (Han, Leichtman, & Wang, 1998; Wang et al., 2000). The story depicted a mother bear and a baby bear dropping off mail, going to the grocery store (where the baby bear briefly loses his mother and gets upset because he wants a cake but is not allowed to have it), and playing in a playground. Mothers were asked to tell the story with their children and to make up the text as they went along. They were also told that they could tell the story in any way they would like and take as long as they wanted to. For Chinese mother–child dyads, time spent on the storytelling task ranged from 3.35 to 15.35 min ($M = 7.29$ min, $SD = 2.79$). For European American mother–child dyads, it ranged from 2.03 to 18.52 min ($M = 7.09$ min, $SD = 3.25$). There was no difference in the mean length of the storytelling between the two cultural groups.

Coding of the story narratives was done in the original language. A native English speaker coded the American data and a native Chinese speaker coded the Chinese data. Repeated training sessions were held to ensure that both coders were applying the same definitions of the coding scheme to the two data sets. A third coder, who was bilingual and fluent in both Chinese and English, independently coded 20% of each data set for reliability estimate. Any disagreements were resolved through discussion.

Following Ruffman et al. (2002), mothers' references to cognitions (e.g., think, know), desires (e.g., want, like, love), modulations of assertions (e.g., might, maybe), emotional states (e.g., sad, pleased), and other mental states (e.g., remember, decide) were separately tabulated. These references were then combined to form a composite category of *mental states language*. Coding for the Chinese data was further informed by research examining mental states language in Chinese children (Lu, Su, & Wang, 2008; Tardif & Wellman, 2000). Terms were counted as referring to mental states when the usage was judged, in context, to be indicative of desires (e.g., 要 yao4), emotions (e.g., 生气 sheng1qi4), cognitions (e.g., 想 xiang3, 知道 zhi1-dao4), other mental states (e.g., 记得 ji4de), and modulations of assertions (e.g., 可能 ke2neng2). Terms that could be interpreted as behavior or mental states (e.g., 看 kan4, equivalent to "see" in English, but may be understood as "think" in Chinese) were coded based on the context. Intercoder reliability indexed by Cohen's kappas ranged from .96 to 1.00 for the Chinese data ($M = 0.98$) and from .87 to .96 for the American data ($M = 0.93$).

Mothers' references to overt behaviors, including physical actions depicted in the book (e.g., running, playing) and potential actions that were not necessarily seen in the book (e.g., he's going to go home now) were coded as *behavioral descriptions*. Cohen's kappas were .83 for the Chinese data and .95 for the American data. This variable further included a subcategory of mothers' references to the behavioral and descriptive manifestations of emotions (e.g., "The bear is crying" and "aw, the bear has tears on his face"). Compared with references to internal emotional states (e.g., "The bear is sad"), behavioral descriptions of emotions focused on external or physical aspects of emotions (Ruffman et al., 2002). Cohen's kappas for this subcategory were .98 for the Chinese data and .87 for the American data. Finally, a "mental-state-to-behavior" ratio was calculated for each mother to form a composite score of *mental states focus*, which controlled for possible influence of narrative length. Children's references to mental states and external behaviors were also coded. However, the frequencies were too low to warrant analysis (see also Slaughter, Peterson, & Mackintosh, 2007) and therefore not considered further.

Language ability. Mothers filled out a shortened version of the Child Development Inventory (Ireton, 1992) that assessed children's language skills. Both expressive language and language comprehension were assessed (possible score range = 0–100; Cronbach's $\alpha = .93$). The questionnaire was translated and back-translated by two English–Chinese bilingual research assistants and checked by a native Chinese speaker to ensure a balance of literal and sense meaning, as well as natural sounding expression. English words and grammatical rules that were not used in Chinese were exchanged for the Chinese equivalents. The inventory was then pilot-tested with seven European American families and five Chinese immigrant families to ensure equivalence. Because children's expressive language score and language comprehension score were highly correlated, $r = .80$, $p < .0001$, they were combined for later analysis. The language measure was included because language ability has been shown to be related to the understanding of emotions and mental states (Happé, 1995).

Maternal education level. As a measure of SES, maternal education was coded on a 3-point scale: 1 = *high school qualification*, 2 = *4-year college degree*, and 3 = *postgraduate degree*.

Children's ESK. Children's ESK was assessed using an emotion production task adapted from previous research examining in different cultures children's ability to understand situations that provoke various emotions (Harris et al., 1987). This task has been used with European American and Chinese preschoolers (Wang, 2008; Wang et al., 2006) and has been shown to be effective in eliciting children's responses regarding the situational antecedents of emotions. Children were asked to describe situations likely to provoke fearful, sad, angry, and happy emotions. The researcher presented each term to the child and asked the child to describe situations that would elicit such an emotion in people (e.g., "What makes people feel sad?") and in the child (e.g., "What makes you feel sad?"). For each question, the researcher prompted the child to provide as many situations as possible (e.g., "What else makes people feel sad?") until the child indicated that that he or she was finished. The researcher rewarded children with stickers to motivate them to come up with as many situations as possible. This task took approximately 10 min.

The number of responses children provided was tallied. Responses were considered correct if the situation described by the child was judged to be able to elicit the presented emotion (e.g., "What makes you feel happy?" "My teddy bear"). This included situations that would elicit the emotion in a child but not necessarily in an adult. In both cultural groups, responses provided by children were mostly correct. Incorrect responses were rare, whereby there was on average less than one incorrect response in each group. On the other hand, not all children could provide a correct response to every emotion. In a few cases, children randomly named objects in the room (e.g., "What else makes people feel happy?'' ''table, chair, cup, . . .''), and these responses were not coded.

The number of correct responses children provided for the four emotions was summed to form a composite score of ESK. A second research assistant coded 20% of the data for reliability. Cohen's kappa, calculated for each child, ranged from .71 to 1.00 ($M = 0.84$) for the Chinese children and from .66 to 1.00 ($M = 0.75$) for the European American children.

Results

Preliminary Analyses

Analyses of mother–child storytelling variables were based on frequencies. Previous research on mother–child interaction has shown that compared with proportion, frequency is more informative in reflecting the sheer amount of different types of information that children are exposed to and is also more predictive of child outcome (e.g., Fivush, 1998; Han et al., 1998; Reese et al., 1993). Ruffman et al. (2002) further argue that each utterance potentially has a direct bearing on children's understanding of mental states because it provides additional input, just in the same way that having multiple older siblings or spending more time with older individuals has a beneficial effect on children's theory of mind (Lewis et al., 1996; Ruffman et al., 1998). In addition, in studies where both frequency and proportion were analyzed, the analyses yielded similar patterns of results (Meins, 2003; Meins et al., 2003; Wang, 2006).

Nevertheless, to ensure that the number of maternal references did not simply reflect overall maternal involvement or verbosity, and hence contributing to children's ESK, we examined the sum of behavioral and mental states references ($M = 63.28$, $SD = 27.08$) as well as the total amount of time spent on the storytelling task ($M = 7.18$, $SD = 3.04$) in relation to children's ESK. Results revealed no significant correlation between the sum of references ($r = .10$, $p = .26$) or the total time spent on the task ($r = .09$, $p = .29$) and children's ESK, thus ruling out the possibility that the overall linguistic input was influencing children's ESK. In addition, there was no significant cultural difference in mothers' total references to mental states and behaviors combined (European American: $M = 66.43$, $SD = 29.01$; Chinese: $M = 59.49$, $SD = 25.26$), $F(1, 128) = 2.14$, $p = .15$, nor in the amount of time mother–child pairs spent on the storytelling task (European American: $M = 7.02$, $SD = 3.15$; Chinese: $M = 7.30$, $SD = 2.79$), $F = (1, 128) = .38$, $p = .50$. Nonetheless, to ensure that cross-cultural differences were not driven by overall maternal involvement or verbosity, we included the amount of time spent on the task as a covariate in analyses wherever appropriate.

Scores for both the composite mental state and behavioral references were positively skewed. Logarithmic transformations were thus performed on these variables before they were submitted to analysis. To facilitate comparisons with previous research, untransformed means are reported.

The following results are presented in accordance with our three hypotheses. The first group of analyses examined group (culture and gender) and individual variations (child age, language skills) in maternal references to mental states and behaviors, as well as in children's ESK. The second set of analyses aimed at determining the relation between types of maternal references (i.e., mental states and behaviors) and children's ESK, independent of other group and individual factors. The final set of analyses tested the mediational role of a mental states focus for cultural influences on children's ESK. Some of the children did not complete all the tasks; thus, the degrees of freedom varied slightly across tests.

Maternal References to Mental States and Behaviors and Child ESK

Table 1 lists the means and standard deviations of mother and child variables by culture. To test our first hypothesis that European American mothers would focus more on mental states whereas immigrant Chinese mothers would focus more on behaviors, we first ran a 2 (culture) × 2 (gender) multivariate analysis of covariance (MANCOVA) on the subtypes of maternal references to mental states (e.g., desires, cognitions), with child age, language ability, maternal education, and time spent on the task as covariates. Consistent with our prediction, the effect of culture was highly significant, $F(6, 116) = 15.67$, $p < .001$, $\eta_p^2 = .45$. There was also an effect of time, $F(6, 116) = 14.19$, $p < .001$, $\eta_p^2 = .42$, suggesting that more time spent on the task was associated with increased maternal input. No other main effects or interactions reached significance.

We then ran separate ANCOVAs to determine the effect of culture on each type of mental state input. As expected, European American mothers made significantly more references to cognitions

Table 1
Means and Standard Deviations of Mother and Child Variables by Culture

	Chinese immigrant		European American	
	M	*SD*	*M*	*SD*

Mental states focus***	0.21	0.12	0.84	0.59

**$p < .01$. ***$p < .001$ (all significance tests are one-tailed).

(think/know), $F(1, 122) = 54.20$, $p < .001$, $\eta_p^2 = .31$; modulations of assertions, $F(1, 122) = 29.97$, $p < .001$, $\eta_p^2 = .20$; emotional states, $F(1, 122) = 5.28$, $p = .02$, $\eta_p^2 = .04$; and other mental states, $F(1, 122) = 10.10$, $p = .002$, $\eta_p^2 = .08$, than did Chinese immigrant mothers. There was no cultural difference in the number of references to desires, $F(1, 122) = 1.23$, $p = .27$, $\eta_p^2 = .01$. There was a main effect of time for references to cognitions, $F(1, 122) = 31.57$, $p < .001$, $\eta_p^2 = .20$; desire, $F(1, 122) = 21.83$, $p < .001$, $\eta_p^2 = .15$; modulations of assertions, $F(1, 122) = 23.14$, $p < .001$, $\eta_p^2 = .16$; emotional states, $F(1, 122) = 6.63$, $p = .01$, $\eta_p^2 = .05$; and other mental states, $F(1, 122) = 6.00$, $p = .02$, $\eta_p^2 = .05$. There were no significant effects or interactions pertaining to gender, age, language, and maternal education.

Consistent with our hypotheses, analysis of the composite mental states language score showed that even after controlling for mothers' education level, time spent on task, child language ability, child age, and gender, European American mothers made significantly more references to mental states than did Chinese mothers, $F(1, 122) = 78.02$, $p < .001$, $\eta_p^2 = .39$.

Next, we analyzed the overall score of behavioral descriptions, with the same covariates. Results showed that Chinese immigrant mothers made more references to behaviors than did European American mothers, $F(1, 122) = 24.83$, $p < .001$, $\eta_p^2 = .16$. Chinese immigrant mothers were also more likely to describe more emotional behaviors than did European American mothers, $F(1, 122) = 23.43$, $p < .001$, $\eta_p^2 = .16$. European American mothers scored higher on mental states focus than did Chinese immigrant mothers, $F(1, 122) = 56.76$, $p < .001$, $\eta_p^2 = .32$. Finally, it is important to note that across both cultures, references to behaviors were more common than references to mental states.

With regard to children's ESK, a 2 (culture) × 2 (gender) ANCOVA with child age and language ability as covariates showed that European American children scored significantly higher than did their Chinese peers, $F(1, 127) = 48.15$, $p < .001$, $\eta_p^2 = .28$. No effects pertaining to gender, age, and language neared significance.

Relation of Maternal References to Mental States and Behaviors to Children's ESK

The second goal of the current study is to examine the relation of maternal mental states language and behavioral references to children's ESK. Zero-order correlations were first calculated to examine the interrelations among maternal references to mental states and behaviors and children's ESK score for each culture. Table 2 reports the zero-order correlations among mother and child variables for each culture. For the European American sample, ESK was positively related to mothers' references to cognitions, the sum total of mental states, and mental states focus. For the Chinese sample, ESK was positively related to total mental states references and mental states focus; albeit the correlations did not reach significance. In addition, ESK was negatively correlated with maternal references to behaviors in the European American sample and negatively correlated with references to emotional behaviors in the Chinese sample. Language was not significantly correlated with ESK in either sample.

Partial correlations were further calculated between maternal variables and children's ESK, controlling for culture, child age, gender, language, maternal education, and time spent on task. Table 3 reports the partial correlations. Independent of the group and individual variables, maternal references to cognitions and maternal mental states focus were positively correlated with children's ESK. In addition, maternal references to behaviors were negatively related to children's ESK score.

Next, *hierarchical* regression analyses were conducted to examine the effects of mental states

language (composite score) and behavioral references on children's ESK, independent of culture, gender, age, language skills, time spent on task, and maternal education. Table 4 reports the summary of results from the regression analyses. We were interested in whether maternal inputs could account for variance in children's ESK independent of group and individual differences. Therefore in the first step of the regression, demographic variables including culture, gender, age, language, and maternal education, along with time spent on task were first entered. These variables combined predicted 34% of the variance in children's ESK, $F(6, 123) = 10.65$, $p < .001$. Next, to see if maternal input would increase the variance explained above these control variables, we added maternal references to mental states and behaviors to Step 2 of the model. Maternal references to mental states and behaviors increased the variance explained to 40%, $F(8, 121) = 9.87$, $p < .001$. Finally, to test whether culture moderated the effects of mental states language and behavioral references, we added the interaction terms of Culture × Mental States and Culture × Behaviors to the model. Neither interaction reached significance, suggesting that the effects of internal states and behaviors were not moderated by culture.

A second set of regression analyses was conducted to examine whether the proclivity to focus on mental states over behaviors (i.e., mental states focus) would predict children's ESK. In the first step of the regression, demographic variables including culture, gender, age, language, and maternal education, along with time spent on task, were first entered. Mental states focus was then added in the second step. Mental states focus significantly predicted children's ESK, $\beta = .22$, $F(6, 123) = 10.22$, $p < .001$, and significantly increased the proportion of variance explained in ESK, $\Delta R^2 = .03$, $F(1, 122) = 10.22$, $p = .02$. Again, we found no moderation effect of culture.

In sum, the results indicated that regardless of culture, maternal use of mental states language positively predicted children's ESK whereas maternal references to overt behaviors were negatively related to children's ESK.

Did Mental States Focus Mediate Cultural Effects on ESK?

Our final set of analyses tested the hypothesis that mothers' proclivity to focus on mental states rather than behaviors would mediate the cultural effect on children's ESK. All regression models controlled for child gender, age, language, maternal education, and time spent on task. The mediation results are summarized in Figure 1. First, to establish conditions for mediation (Baron & Kenny, 1986), culture (i.e., the independent variable) was examined as a predictor of children's ESK (i.e., the criterion); the result was significant, $F(6, 122) = 10.65$, $p < .001$. European American mothers also scored higher than Chinese mothers on mental states focus (i.e., the mediator), $F(6, 123) = 12.62$, $p < .001$, and mental states focus positively predicted children's ESK independent of culture, $F(6, 123) = 7.3$, $p < .001$. Finally, when both mental states focus and culture were entered into the model as predictors, the effect of culture on ESK was reduced in size, although still significant, $p < .001$. The reduction was significant by the stringent Sobel's (1982) test for mediation, $Z = -4.29$, $p < .001$. In sum, maternal mental states focus mediated, at least partially, the effect of culture on children's ESK.

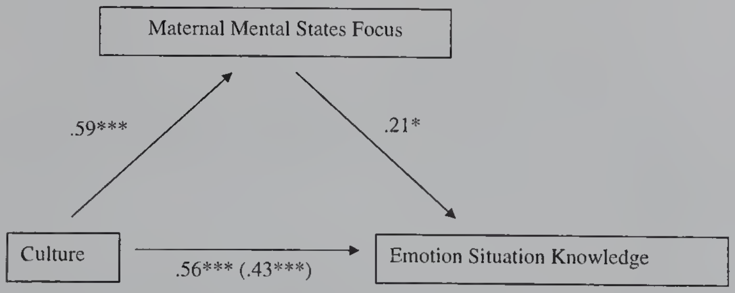

Figure 1. Mental states focus mediated the effect of culture on children's emotion situation knowledge.
Note. Regression models controlled for child gender, age, language, mothers' education, and time spent on task. The coefficient in parentheses was from the regression when the mediator (mental states focus) was included in the equation.

Discussion

The present study is the first to examine, in a cross-cultural context, maternal references to mental states and external behaviors during narrative interactions with their children and the relations of these maternal references to children's ESK. The results revealed varied narrative practices across cultures, which further differentially affected ESK in children. As predicted, European American mothers used significantly more mental states language than did Chinese immigrant mothers, whereas Chinese immigrant mothers made more references to behaviors than did European American mothers. The differences held true even when mothers were talking about emotions; European American mothers referred more frequently to internal emotional states, whereas Chinese immigrant mothers described more physical and behavioral manifestations of emotions.

The results are consistent with previous research demonstrating that during conversations with their young children, Chinese mothers often place an emphasis on external behaviors and actions, whereas European American mothers tend to focus on the child's internal attributes, thoughts, and feelings (Fivush & Wang, 2005; Wang, 2001). European American mothers' tendency to emphasize thoughts and feelings may reflect the cultural assumption that language is a mechanism for expression, specifically of one's mental states, whereas Chinese mothers' focus on behaviors may exemplify the importance of language as a mechanism for "guiding actions and social interaction" (Hansen, 1983, p. 85). In addition, the emphasis on mental states places importance on individual realities and states of being, reflecting European American cultural values of individuality and autonomy (Wang et al., 2000). On the other hand, behavior-descriptive terms emphasize individuals' explicit actions and relations to the physical and social contexts (Maas et al., 2006).

Notably, although there were cultural differences in most aspects of mental states references, there was no difference in maternal references to desires. Although desires are considered a mental state, they have clear implications for behaviors. Because of this advantage, children acquire verbs for desires before they acquire verbs for thoughts and beliefs (Bartsch & Wellman, 1995), and by the early preschool age children have demonstrated an understanding of simple desires (Repacholi & Gopnik, 1997; Wellman et al., 2000). Given that desire terms have important implications from both a psychological and a behavioral perspective, it makes sense that mothers from both cultures would readily use desire terms in conversations with their young children. Interestingly, research examining Chinese children's use of mental states language has shown that although they acquire desire terms earlier than their European American peers, they lag behind in terms related to cognitions (Tardif & Wellman, 2000). Furthermore, there is some evidence to suggest that Chinese children's early vocabulary contains more verbs than nouns (Choi & Gopnik, 1995; Tardif, 1996). These findings may be explained by the Chinese pattern of maternal input found in our study. The maternal emphasis on behaviors and desires may facilitate Chinese children's learning of verbs and desire terms, respectively, whereas the lack of maternal references to cognitions may impede the children's acquisition and hence expression of thoughts and beliefs.

As expected, across the cultural groups, mothers' use of mental states language was positively associated with children's ESK, consistent with previous research with Western samples (Taumoepeau & Ruffman, 2006, 2008). Furthermore, our results showed that maternal references to behaviors were negatively associated with children's ESK. Indeed, mothers' proclivity to focus on mental states as opposed to behaviors partially mediated the cultural effect on children's ESK. Although mental states language encourages children to reflect on thoughts, desires, and feelings of themselves and others and thus facilitates their understanding of cognitive and affective states (Symons, 2004), behavioral descriptions may draw children's attention to external and contextual factors and therefore may hinder their emotional understanding. Furthermore, the emphasis on mental states argues for the notion that individual behavior can be understood in terms of inner desires, emotions, and thoughts, and that people can be understood in terms of their psychological states (Flavell, 1988). By using language to make explicit the connections between the internal and the external, maternal references to mental states may aid in children's understanding of the psychological causes and antecedents of emotions. References to behaviors are more likely to draw attention to physical realities and social relations and thus may undermine the importance of psychological states, including one's own and others' emotions.

The differential focus on mental states versus behaviors in socialization practices may reflect cultural variations in folk psychology (Lillard, 1998; Miller, 1984). In Western cultures, the locus of the self is thought to lie in mental attributes of the person, such as attitudes, preferences and motives, and mental states are considered important means of understanding others' behaviors (Choi, Nisbett, & Norenzayan, 1999). In contrast, Eastern cultures place the self in context and stress the importance of proper behaviors and actions based on interpersonal norms and social rules (Shweder, 1998). The different narrative practices found in our study suggest that children's attention is directed toward different aspects of the individual, with Chinese mothers emphasizing behaviors whereas European American mothers stressing psychological states. It is important to note, however, that cultural differences in the emphasis on internal versus external attributes are relative rather than absolute—mothers in both cultures used more behavioral descriptions than mentalistic descriptions.

Consistent with a host of recent studies (Adrian, Clemente, & Villanueva, 2007; Ensor & Hughes, 2008; Taumoepeau & Ruffman, 2008), we found maternal references to cognitions to be the strongest correlate with preschool children's emotional understanding. Also similar to some previous work (Ensor & Hughes, 2008; Taumoepeau & Ruffman, 2006, 2008), our study did not find a significant link between maternal references to emotions and children's emotional understanding. We speculate that this might be related to the particular task context involved in the studies. In particular, our book-reading task was not inherently emotional in nature, and mothers might focus on children's thoughts and opinions concerning the story happening rather than their emotions. Indeed, mothers in our study referred to cognitions more than four times as often as emotions. Thus, references to cognitions may be more indicative of maternal mind-mindedness in this particular context (Meins et al., 2002) and is therefore more related to children's emotional understanding. Additionally, in the current study maternal mental state language in reference to emotions mainly captured mothers' labeling of emotions. It is possible that explicit discussion of the causes of feeling states is more effective in helping children understand the situational antecedents of emotions. Future research should directly examine the effect of different contexts in which specific mental state references are used, as well as the different *ways* that parents use mental state language. This will help to further our understanding of the contribution of mental state language to children's emotional understanding.

Results from the current study further demonstrate that the relative emphasis on mental states versus behaviors in mother–child narrative interactions was an important mechanism underlying cultural differences in children's ESK. Nevertheless, the mediation was only partial, and culture remained a highly significant contributor to children's ESK after maternal mental states focus was controlled. Thus, although maternal mental states language may aid children's emotional understanding, it may be only one of a host of factors that may play important roles. For example, research has demonstrated cross-cultural differences in emotional experience including intensity, expression, and evaluation of emotions (Matsumoto, Kudoh, Scherer, & Wallbott, 1988; Scherer, Matsumoto, Wallbott, & Kudoh, 1988). There have been very few studies examining how these differences may play out in socialization practices and further affect children's developing emotional understanding.

Furthermore, our study only utilized one ESK task and that required verbal responses. Perhaps Chinese children were unable or unwilling to speak out their thoughts and, as a result, cultural differences in children's performance on the task might reflect their expressiveness or willingness to communicate rather than their actual emotional understanding. This interpretation is unlikely, however, given that past research has shown that Chinese children are as verbal as European American children in tasks that require self-expression (Han et al., 1998; Wang, 2004; Wang & Leichtman, 2000). In addition, controlling for language ability in analysis did not change the pattern of results. Nevertheless, it is important for future cross-cultural studies to use a variety of emotion tasks, including the ones that require only behavioral responses. Also notably, knowledge of emotion is a broad term involving a host of factors, and we examined only one aspect. In a recent review, Pons, Harris, and de Rosnay (2004) point out that there are at least nine distinct components of emotion knowledge in relation to emotion recognition, perception, and regulation. It is unclear from extant data the extent to which mothers' mental states language has an effect on these various components. Furthermore, the type of maternal input that may be useful is likely to vary as a function of developmental period. For example, maternal emotional expression may be more important than linguistic inputs (such as mental states language) for early understanding of emotions during infancy because of limited language abilities in infants (Friend, 2001). Future research should examine possible interactions among types of maternal input, periods of development, and how they relate to different aspects of emotional understanding in children. In addition, research in the area of mental states language would benefit by examining the extent to which maternal references to mental states may have an effect on children's social cognition (e.g., theory of mind and emotional understanding) or a broad effect on cognitive abilities in general.

It should also be noted that our study only examined one time point. The data were therefore correlational in nature, and causal conclusions cannot be drawn with regard to the influences of maternal use of mental states language and behavioral references on children's ESK at either individual or cultural level. In addition, previous research suggests that mothers tend to increase their references to cognitions as children get older, thus pitching their talk to the developmental level of the child (Taumoepeau & Ruffman, 2008). Although it is possible, then, that mothers (or Chinese mothers as a group) made fewer references to cognitions because their children (or Chinese children as a group) had lower level of general cognitive abilities or language skills, this interpretation is unlikely given that maternal references to cognitions were not related to child age or language skills in the current sample and that they were positively related to ESK independent of child age and language. Additionally, previous research examining maternal talk with preverbal infants (Meins et al., 2002) and studies that controlled for children's conversational input (Ruffman et al., 2002) have shown that the type of maternal input cannot be entirely attributed to child characteristics. Nevertheless, the bidirectional influence between mother and child cannot be completely ruled out from the current data. Further research with longitudinal approaches and experimental designs is called for. Such research will not only help to establish causality but also reveal trajectories of different mental states language usages as children develop in different cultural contexts.

Finally, it is important to further examine the effects of differential socialization emphases on immigrant children straddling two cultures. How does acculturation influence the ways in which immigrant parents interact with their children? What are the sociocognitive consequences of being raised in a family context that is different from the mainstream? These questions will help us further understand the dynamic processes of human development as taking place within multiple contexts and settings where children actively acquire cultural knowledge and eventually become competent members of their society.

The Effects of Maltreatment and Neuroendocrine Regulation on Memory Performance

Dante Cicchetti

Sheree L. Toth
University of Rochester

This investigation examined basic memory processes, cortisol, and dissociation in maltreated children. School-aged children (age range = 6–13), 143 maltreated and 174 nonmaltreated, were administered the California Verbal Learning Test–Children (D. C. Delis, J. H. Kramer, E. Kaplan, & B. A. Ober, 1994) in a week-long camp setting, daily morning cortisol levels were assessed throughout the duration of camp, and behavioral symptoms were evaluated. Maltreatment and cortisol regulation were not related to short- or long-delay recall or recognition memory. However, children experiencing neglect and/or emotional maltreatment and low cortisol evinced heightened false recognition memory. Dissociative symptoms were higher in maltreated children; however, high dissociation was related to recognition inaccuracy only among nonmaltreated children. Results highlight the interplay between maltreatment and hypocortisolism in children's recognition memory errors.

Do maltreated children's basic memory processes operate in ways that are fundamentally different from those of nonmaltreated children? Despite the importance that answers to this question hold for advancing research, clinical, and sociolegal issues in the field of child maltreatment (Howe, 2000; Howe, Goodman, & Cicchetti, 2008; Howe, Toth, & Cicchetti, 2006; Toth & Cicchetti, 1998), there has been a paucity of studies, most of which have been published in recent years, that have examined basic memory processes in maltreated children (Howe, Cicchetti, & Toth, 2006).

Child Maltreatment and Memory

There are a number of reasons why the experience of child maltreatment might be expected to alter basic memory processes (Howe, Toth, et al., 2006). Child abuse and neglect are stressful and threatening experiences that may bring about physiological changes in the neural mechanisms related to memory storage (Bremner & Narayan, 1998; Cicchetti, Rogosch, Gunnar, & Toth, 2010; Howe, Cicchetti, et al., 2006). Moreover, a number of the socioemotional sequelae of child maltreatment, including the development of insecure, often disorganized, attachment relationships and deviations in symbolic and representational abilities (Cicchetti & Toth, 2005), may affect the processing of memories in abused and neglected children (Lynch & Cicchetti, 1998; Pollak, Cicchetti, & Klorman, 1998; Rieder & Cicchetti, 1989). In addition, it is conceivable that failures in caregiving may lead maltreated children either to defensively distort memories or to dissociate their memories of their abusive and neglectful experiences (Cicchetti & Valentino, 2006). Finally, maltreated children are at heightened risk for the development of trauma-related psychopathology, including posttraumatic stress disorder (PTSD) and dissociation, that may contribute to deficits in memory performance (Cicchetti & Toth, 2005; Howe, Toth, et al., 2006).

The majority of the investigations on the effects of maltreatment experiences on memory have focused on examinations of adults who retrospectively report having been abused during their childhoods, adults with PTSD, nonmaltreated

children participating in analog experiments, or individuals with relatively acute and/or routine stressors involving treatment for accidental injuries or visits to physicians' offices (Howe, 2000; Toth & Cicchetti, 1998). Among the studies of memory in adults who report having been maltreated, several investigations have used the Deese–Roediger–McDermott (DRM) paradigm (Deese, 1959; Roediger & McDermott, 1995) to examine false memories in adults who report having been maltreated in childhood and in adults who did not experience maltreatment (for a review, see Howe, Toth, et al., 2006). Each of these investigations found that adults who report histories of maltreatment evinced a higher frequency of false recognition memory errors (i.e., inaccurately recognizing words not previously presented as heard) than did nonmaltreated comparison individuals.

Despite the fact that there have been relatively few studies of basic memory processes in maltreated children conducted to date, a review of the extant literature reveals that the experience of child abuse and neglect does not appear to exert any special effects on memory that fundamentally change the operation of memory from that observed in nonmaltreated children (Howe, Toth, et al., 2006). For example, no differences have been found in investigations of maltreated children's memory for eyewitnessed events or in their degree of susceptibility to misinformation and suggestion, unless accompanying comorbid psychopathology is present (Eisen, Goodman, Qin, Davis, & Crayton, 2007; Eisen, Qin, Goodman, & Davis, 2002; Howe, Toth, et al., 2006).

In an investigation of true and false recall memory in maltreated children, Howe, Cicchetti, Toth, and Cerrito (2004) examined the memory performances of maltreated and nonmaltreated children on the DRM task. The same pattern of results was found regardless of maltreatment status. Consistent with the normative literature on false memory (Brainerd & Reyna, 2005), both maltreated and nonmaltreated children exhibited false recognition memories and memory inaccuracies with age at the same rate. Similarly, Porter, Lawson, and Bigler (2005) found no significant differences in memory function between sexually abused and nonabused children, despite elevations in psychopathology and diminished performance on measures of attention and executive function for the abused group. Additionally, Beers and DeBellis (2002) did not find any between group differences in basic memory processes for maltreated children and adolescents with PTSD and normative comparison youth. Overall, because these investigations focused on group differences, studies that examine within-group differences might yield different results. Not all maltreated individuals are equally affected by their traumatic experiences (Cicchetti & Toth, 2005). Thus, investigations of basic memory processes in children who have experienced sexual and physical abuse, neglect, and emotional maltreatment are warranted.

Toward this end, a depth-of-processing incidental recall task was used to examine self-relevant information among maltreated children and the relation between maltreatment and false recall on dissociation (Valentino, Cicchetti, Rogosch, & Toth, 2008b). Abused, neglected, and nonmaltreated children all demonstrated better recall for words when words were encoded under self-referent conditions rather than under structural conditions. These results suggest that self-representations serve as an organizing schema for memory and may be used to facilitate recall (cf. Howe, 1998, 2000). Consistent with prior research (Howe et al., 2004), differences were not found among abused, neglected, or nonmaltreated children in the occurrence or total amount of false recall errors. Maltreated children were not rendered more or less susceptible to false recall errors (cf. Howe et al., 2004).

Notably, however, the younger group of neglected children demonstrated a greater proportion of negative false recall errors and less positive recall than did the younger abused children, suggesting a greater vulnerability for memory inaccuracy among neglected children. Among the older group, both abused and neglected children demonstrated less positive false recall than did the nonmaltreated children. Negative self-schemas were associated with increased dissociation among the abused children, whereas positive self-schemas were related to increased dissociation for the neglected children. In addition to addressing the role of dissociation on memory, it also is important to attend to possible neurobiological influences.

HPA-Axis Functioning and Memory

Child abuse and neglect are stressful and threatening experiences that create adaptational challenges (Cicchetti & Rogosch, 2001a; DeBellis, 2001; Hart, Gunnar, & Cicchetti, 1996). One of the physiological systems that has evolved in mammals to help direct and sustain cognitive, emotional, and behavioral activity in response to threat and stress is the hypothalamic–pituitary–adrenal (HPA) axis. Basal levels of cortisol, usually referred to as the "stress hormone," are necessary for normal neurobiological growth and for the support of the metabolic activity necessary to sustain general functioning (McEwen, 1998). Among its many influences, cortisol affects the central neural processes that are implicated in cognition, emotion, and memory (Gunnar & Vazquez, 2006).

Brief elevations in cortisol following acute stressors enhance the individual's ability to manage stressful experiences competently, both physiologically and behaviorally (Lopez, Akil, & Watson, 1999; Vazquez, 1998). However, chronic hyperactivity of the HPA axis may eventuate in a number of negative biological and psychological outcomes, including the loss of hippocampal neurons and impaired affective and cognitive functioning (Sapolsky, 1992, 1996). Although studies of the effects of stress on HPA functioning in humans are less well controlled than are those conducted with animals, hippocampal atrophy is associated with prolonged exposure to glucocorticoids, a class of steroid hormone that includes cortisol. Furthermore, chronic exposure to elevated levels of glucocorticoids is accompanied by cognitive problems, including impairment of declarative memory and visual episodic memory (for reviews, see Heffelfinger & Newcomer, 2001; Howe, Toth, et al., 2006).

Additionally, there is a phenomenon known as hypocortisolism in which individuals who have experienced chronic stress, such as ongoing maltreatment, may exhibit reduced adrenocortical secretion, reduced adrenocortical reactivity, or enhanced negative feedback inhibition of the HPA axis (Gunnar & Vazquez, 2001; Heim, Ehlert, & Hellhammer, 2000; Miller, Chen, & Zhou, 2007). This flattening of the diurnal decrease in cortisol predicts heightened risk of impairment in cardiovascular and immune system functioning (Heim, Newport, Mletzko, Miller, & Nemeroff, 2008). Since it is firmly established that the glucocorticoid cortisol affects the aspects of brain function such as visual episodic memory, just as is the case with hypercortisolism, hypocortisolism also may exert negative impacts upon brain development and cognitive functioning. To the best of our knowledge, to date there have been no studies conducted on the association between memory performance and hypocortisolism, either in maltreated or nonmaltreated children.

Studies cohere in the conclusion that the HPA axis of maltreated children is often characterized by regulatory difficulties (Tarullo & Gunnar, 2006). Although studies have not revealed differences in cortisol regulation between maltreated and nonmaltreated children, differences have emerged when maltreatment subtype is examined. For example, children who have been extensively maltreated (i.e., experienced sexual and physical abuse, plus neglect and/or emotional abuse) have been found to exhibit substantial elevations in morning cortisol levels (Cicchetti & Rogosch, 2001a); children in the multiple abuse (sexual and physical) group also have been shown to display elevations in cortisol levels in both the morning and afternoon (Cicchetti & Rogosch, 2001a). In contrast, maltreated children who have been physically abused, in the absence of sexual abuse, have been shown to exhibit low levels of cortisol. Thus, not all maltreated children exhibit the same patterns of cortisol regulation (Cicchetti, 2002). Hypercortisolism and hypocortisolism are likely outcomes of HPA-axis dysregulation, while some maltreated children display what appears to be normal cortisol regulation (Cicchetti & Rogosch, 2001a; Tarullo & Gunnar, 2006).

Animal models of the impact of early caregiving adversity have predominantly focused on increased reactivity of the HPA axis on outcome (Heim, Owen, Plotsky, & Nemeroff, 1997; Sanchez, Ladd, & Plotsky, 2001; Sanchez et al., 2005). However, as the research has been extended to human and nonhuman primates, it has become increasingly clear that a more accurate prediction is that the HPA axis will likely exhibit evidence of *dysregulation* and that this dysregulation may involve both hyper- and hypofunctioning (Heim, Plotsky, & Nemeroff, 2004; McEwen, 2000). Although not yet fully understood, a number of factors have been shown to affect whether elevated or suppressed cortisol occurs. The HPA axis tends to dysregulate in response to prolonged hyperactivation; thus, in response to chronic stressors, first hyper- and later hypoactivity of the axis may be noted (for a review, see Miller et al., 2007). Accordingly, hypercortisolism is more likely to occur as a result of acute stress and a shorter time since the onset of stress or maltreatment, whereas hypocortisolism is likely the result of a long-term process of chronic stress and a later time since the onset of stress or maltreatment.

Very few studies have examined stress and memory in normative samples of children (Bremner & Narayan, 1998; Bremner & Vermetten, 2001; Howe, Toth, et al., 2006). The only investigation that has examined cortisol and memory in maltreated children conducted to date is that of Eisen et al. (2007). In the Eisen et al. study, maltreated and nonmaltreated comparison children's memory and suggestibility were assessed for an invasive medical procedure that had been administered to them as part of a child abuse and neglect investigation. At the conclusion of the medical examination, older (as compared to younger) children and those who possessed higher cognitive functioning exhibited fewer memory inaccuracies and less suggestibility in their responses to experimenter questions that focused on the recollection of events that were associated with the medical procedures that had been administered. For children low in dissociative symptomatology, higher levels of cortisol reactivity, assessed approximately 20 min after the medical procedures, were found to be related to fewer errors of omission to specific questions about the medical examination and to fewer errors of commission to the experimenter's misleading questions.

In contrast, for children who reported high levels of dissociative symptoms, higher levels of cortisol reactivity were related to more errors of omission to specific questions about the medical procedure and to more errors of commission to misleading questions of the experimenter. Although the initial findings of the Eisen et al. (2007) study are suggestive, limitations in the method of cortisol sampling, lack of cortisol collection for a sizable portion of the sample, and the very specific episodic memory assessment indicate that further research on cortisol, memory, and dissociation in maltreated children is necessary.

An interesting finding that emerged was that children who had experienced sexual and/or physical abuse evinced greater memory accuracy than did those who had experienced child neglect. Specifically, the sexually and/or physically abused children were less suggestible than were the neglected children when confronted with misleading questions about the medical examination, exhibited fewer errors of omission to questions about abuse-related incidents, and provided more correct answers in response to open-ended questions about the medical procedures. It may be the case that abuse contributes to greater vigilance and monitoring of experience and consequently to greater precision in memory encoding and retrieval.

In summary, because child maltreatment experiences do not affect all abused and neglected individuals in the same fashion (known as multifinality; see Cicchetti & Rogosch, 1996), there are likely to be within group differences in memory performance among children with varying maltreatment subtypes. The chronic stress of maltreatment suggests that the cortisol dysregulation characteristic of many maltreated children may be a potential risk for recognition memory inaccuracies in these youngsters. Furthermore, neglected children may be more susceptible to recognition memory errors than are abused children (Eisen et al., 2007; Valentino et al., 2008b). Finally, dissociation appears to be either related to, or an independent contributor to, recognition memory inaccuracies.

In the present article, we report the results of an investigation that examines the relation among neuroendocrine regulation, memory, and dissociative symptoms in maltreated children. We expect the memory performance of maltreated children to differ in relation to varying levels of cortisol regulation. Specifically, we examine the extent to which maltreated children's basic recognition memory processes differ from those of a group of demographically comparable nonmaltreated children. We then investigate the relation between these basic memory processes and individual differences in neuroendocrine functioning and dissociation in maltreated and nonmaltreated children.

This research is guided by the following hypotheses and research questions:

1. In accord with the extant literature, we expected that maltreated children's basic recall and recognition memory skills would not differ from those of nonmaltreated children.
2. We did not expect to find group mean differences between maltreated and comparison children in average morning cortisol levels; however, more extreme patterns of atypical cortisol regulation were expected in physically and/or sexually abused children.
3. We expected that maltreated children with either low morning cortisol or high morning cortisol, suggesting neuroendocrine dysregulation, would have more false recognition memory than nonmaltreated children. Based on the Eisen et al. (2007) and Valentino et al. (2008b) findings, we hypothesized that this relation would be particularly true for children who experienced physical neglect and/or emotional maltreatment but not physical and sexual abuse.
4. Finally, we expected that high levels of dissociation would be related to anticipated differences in memory performance based on maltreatment subtype and cortisol regulation patterns.

Method

Participants

The participants in this investigation included 317 children who attended a recreational summer camp program designed for school-aged low-income, maltreated ($n = 143$) and nonmaltreated ($n = 174$) children. Two cohorts of children from different camp years were aggregated for the current study. In addition to recreational activities, the annual summer camp program incorporated research assessments. The children on average were 9.17 years of age ($SD = 2.43$, range = 6–13), and 54.6% were boys. The racial/ethnic composition of the sample was diverse: 56.6% were Black, 21.5% were White, 17.0% were Latino, and 1.9% were of other racial/ethnic backgrounds.

Parents of all maltreated and nonmaltreated children provided informed consent for their child's participation, as well as consent for examination of any Department of Human Services (DHS) records. Children in the maltreated group had been identified by the county DHS as having experienced child abuse and/or neglect, and the sample was representative of the children in families receiving services from the DHS. A recruitment liaison from DHS contacted eligible maltreating families and explained the study, and if parents were interested their names were released to the project team for recruitment. Comprehensive searches of DHS records were completed, and maltreatment information was coded utilizing operational criteria contained in the Barnett, Manly, and Cicchetti (1993) nosological system for child maltreatment. Children in the maltreated group were living in their family homes and not residing in foster care.

Consistent with national demographic characteristics of maltreating families (NIS–3; Sedlack & Broadhurst, 1996), the maltreated children were predominantly from low-socioeconomic-status families. Accordingly, a demographically comparable sample of nonmaltreated children was recruited from families receiving Temporary Assistance to Needy Families. A DHS recruitment liaison contacted eligible nonmaltreating families and described the project, and if interested, parents signed a release for their names to be given to the project for recruitment. DHS record searches were completed for these families to verify the absence of any record of child maltreatment. Trained research assistants also interviewed mothers of children recruited for the nonmaltreatment group to confirm a lack of DHS involvement and prior maltreatment experiences (Cicchetti, Toth, & Manly, 2003). Subsequently, record searches were conducted in the year following camp attendance to verify that all available information had been accessed. Only children from families without any history of documented or mother-reported abuse and/or neglect were retained in the nonmaltreatment group. In addition, families who had received preventive services through DHS due to concerns over risk for maltreatment also were excluded from the nonmaltreated comparison group to reduce the potential for unidentified maltreatment existing within this group.

Table 1 presents demographic information for families of children in the maltreated and nonmaltreated groups. The groups were comparable on a number of family characteristics. The maltreated and nonmaltreated groups did not differ in terms of total family income, including public assistance, $t(305) = 1.45$, $p = .15$; maternal marital status, $\chi^2(2) = 4.95$, $p = .08$; or maternal education, $\chi^2(1) = 3.11$, $p = .08$. Overall, the majority of families in both groups were headed by a single parent, and most mothers had a high school education or less. Family income was limited, and across the families, 73% were currently receiving public assistance.

Procedure

Children attended a week-long day camp program, participated in research assessments, and took part in a variety of recreational activities. The camp was not designed to provide a therapeutic intervention experience. After providing assent, children participated in various research assessments (see Cicchetti & Manly, 1990, for detailed descriptions of camp procedures). Children were administered the specific measures of interest in the current report, the California Verbal Learning

Table 1
Family Demographic Features

	Nonmaltreated	Maltreated
	M (*SD*) or %	*M* (*SD*) or %
Marital status		
Never married	35.7%	28.2%
Married/living together	42.1%	38.7%
No longer married	22.2%	33.1%
Maternal education		
High school or less	52.0%	62.0%
Total family income		
$1,000s including public assistance	24.81 (12.37)	22.86 (10.90)

Test–Children (CVLT–C) and the Peabody Picture Vocabulary Test–III (PPVT–III), on different days during the camp week. At the end of each week, counselors who worked with the children rated them on behavioral symptomatology.

Measures

Maltreatment classification system. The Maltreatment Classification System (MCS; Barnett et al., 1993) was used to delineate diverse features of maltreatment experienced by individual children. The MCS utilizes DHS records detailing investigations and findings involving maltreatment in identified families over time. Rather than relying on official designations and case dispositions, the MCS codes all available information from DHS records, making independent determinations of maltreatment experiences. Based on operational criteria, the MCS designates all of the subtypes of maltreatment children have experienced (i.e., neglect, emotional maltreatment, physical abuse, sexual abuse), the perpetrator(s) of the maltreatment, the severity of each subtype, frequency of occurrence, and the developmental periods of occurrence, allowing for determination of onset, recency, and chronicity.

In terms of the subtypes of maltreatment, *neglect* involves failure to provide for the child's basic physical needs for adequate food, clothing, shelter, and medical treatment. In addition to inadequate attention to physical needs, forms of this subtype include lack of supervision, moral-legal neglect, and educational neglect. *Emotional maltreatment* involves extreme thwarting of children's basic emotional needs for psychological safety and security, acceptance and self-esteem, and age-appropriate autonomy. Examples of emotional maltreatment of increasing severity include belittling and ridiculing the child, extreme negativity and hostility, exposure to severe marital violence, abandoning the child, and suicidal or homicidal threats. *Physical abuse* involves the nonaccidental infliction of physical injury on the child (e.g., bruises, welts, burns, choking, broken bones). Injuries range from minor and temporary to permanently disfiguring. Finally, *sexual abuse* involves attempted or actual sexual contact between the child and caregiver for purposes of the caregiver's sexual satisfaction or financial benefit. Events range from exposure to pornography or adult sexual activity, to sexual touching and fondling, to forced intercourse with the child.

Coding of the DHS records was conducted by trained research assistants, doctoral students, and clinical psychologists. Coders were required to meet acceptable reliability with criterion standards before coding actual records for the study. Coders demonstrated acceptable reliability (weighted κs with the criterion = .86 to .98). Reliabilities for the presence versus absence of maltreatment subtypes (κs = .90–1.00) also were established. Other investigators have demonstrated that the MCS is reliable and valid in classifying maltreatment (Bolger, Patterson, & Kupersmidt, 1998; Dubowitz et al., 2005; English et al., 2005; Manly, 2005; Smith & Thornberry, 1995).

Among the maltreated children, 79.7% had experienced neglect, 73.4% had experienced emotional maltreatment, 36.4% had experienced physical abuse, and 14.7% had experienced sexual abuse. Thus, neglect and emotional maltreatment had occurred frequently among most of the maltreated children, whereas lower prevalence rates were found for physical and sexual abuse. As is typical in maltreated populations (Bolger et al., 1998; Manly, Cicchetti, & Barnett, 1994; Manly, Kim, Rogosch, & Cicchetti, 2001), the majority of children had experienced multiple subtypes of maltreatment. Specifically, 68.5% of the maltreated children had experienced two or more maltreatment subtypes ($M = 2.04$, $SD = 0.89$), and 14 of the 15 possible combinations of the four maltreatment subtypes were observed in the sample. In order to consolidate groups for comparison purposes, we sought to differentiate children whose maltreatment experiences had involved physical and/or sexual abuse with or without neglect and emotional maltreatment (PA/SA; $n = 61$) from those who had not been physically or sexually abused but had been neglected and/or emotionally maltreated (PN/EM; $n = 82$). Within the PA/SA group, 75.4% had been emotionally maltreated and 82.0% had been neglected. Comparable rates of emotional maltreatment (72.0%) and neglect (78.0%) were observed in the PN/EM group. Thus, what distinguished the PA/SA group from the PN/EM group was the presence of abuse.

Salivary cortisol. The camp context provided a setting where a consistent collection of saliva samples could occur at uniform times across the camp week. Each day upon arrival to the camp at 9:00 a.m. trained research assistants obtained saliva samples from each child. The children had not consumed food or drink for at least 30 min before each saliva sample was obtained. Given the approximate 45-min transportation time and the time spent being greeted by camp staff, children had been awake at least 1 hr prior to providing the morning saliva samples. Because cortisol levels are volatile and sharply rise and fall during the first hour after morning awakening (cf. Susman et al., 2007), the timing of morning samples likely occurred when relative stability in morning level was established, before gradually declining over the course of the day. Although we were not able to obtain daily wake-up times for children, there is no reason to suspect that wakening times systematically varied across groups.

Two different saliva collection procedures were used depending on the child's cohort membership. In the first cohort involving 49.8% of the participants, Kool-Aid crystals were administered to stimulate saliva flow, mouthing of a sterile cotton dental role to soak up the saliva, with subsequent expressing of the saliva from the dental role into storage vial via a syringe at −80 °C. Cortisol assays were conducted at the University of Minnesota utilizing the Ciba Corning Magic Cortisol Kit. For the second cohort, children deposited saliva through a small straw directly into storage vials. The samples were analyzed at Pennsylvania State University using a high-sensitive enzyme immunoassay (Salimetrics, PA).

Because of the difference in assay method and variation in the distribution of assay results in different cohorts, standardized scores were used to calibrate samples across cohorts. As is typical, high kurtosis and negative skew characterized the distributions of cortisol values each year. As a result, all values were transformed using log10. Within each year, all log10-transformed values were converted to Z scores. The standardized scores thus allowed for relative comparability in cortisol levels across camp years (cf. Cicchetti & Rogosch, 2001a, 2001b). All morning values for each child were averaged to derive a mean morning cortisol variable. The two cohorts did not differ on demographic characteristics, cortisol levels, memory variables, or dissociation.

California Verbal Learning Test–Children. The CVLT–C (Delis, Kramer, Kaplan, & Ober, 1994) provides an assessment of strategies and processes involved in learning and recall of verbal material. The test is individually administered and normed for children aged 5–16. It is used to assist in the diagnosis and treatment of memory impairments. The CVLT–C provides the indices of verbal learning and recall and recognition memory. The CVLT–C was developed and standardized on a representative sample of the U.S. population, and reliability and validity have been established (Delis et al., 1994). Completion time for the CVLT–C was approximately 50 min.

In the first five trials, children are read a list of 15 words from three nonaffective semantic categories (i.e., things to wear, things to play with, fruits) and then are asked to recall as many words as they can. An interference trial of 15 new words is then presented. Children are then requested to freely recall the words from the original list and then are given a subsequent trial in which semantic cues to the words are presented to facilitate recall. A 20-min delay involving a nonverbal activity occurred next. Children then are directed to recall the original word list, followed by another cued recall trial. Finally, children were presented with a serial list of 45 items and asked to determine whether each word was on the original list. In the current report, children are compared on their abilities in short-delay recall, long-delay recall, recognition memory, and false positive memory recognition. A discriminability index, comparable to d', which assesses children ability to distinguish target words from distractor words, also was evaluated. Age standardized scores for all memory variables were used. Finally, deficits in retrieval (low standard scores for long-delay recall and normal standard scores for discriminability) and encoding (low standards scores for both long-delay recall and discriminability) also were examined.

Peabody Picture Vocabulary Test–III. The PPVT–III (Dunn & Dunn, 1997) assesses children's receptive vocabulary abilities. The PPVT–III correlates with the Full Scale IQ of the Wechsler Intelligence Test for Children (WISC–III). The PPVT–III was completed in approximately 15 min.

Teacher Report Form and Dissociation subscale. Behavioral symptomatology was evaluated at the end of each week by camp counselors' completion of the Teacher Report Form (TRF; Achenbach, 1991) after approximately 35 hr of observation and interaction with the children. The camp counselors were unaware of maltreatment status and research hypotheses. The TRF is a widely used and validated instrument to assess behavioral disturbance from the perspective of teachers, and the measure was used in the present study, because camp counselors are able to observe similar behaviors to that of teachers. The TRF, containing 118 items rated for frequency, assesses a broad range of symptoms. In the present study, interrater reliability for total behavior problem scores, based on average intraclass correlations among pairs of raters, ranged from .78 to .87 (M = 0.82). Ogawa, Sroufe, Weinfield, Carlson, and Egeland (1997) developed a subscale to assess dissociative symptoms in childhood and adolescence based on 12 TRF items. The content of these items is similar to those assessed by the *Child Dissociative Checklist* (Putnam, Helmers, & Trickett, 1993). The counselors' scores for the dissociation subscale items for each child were averaged to derive individual child scores for dissociative symptomatology.

Results

Maltreatment and Cortisol Dysregulation

Overall, as found in previous work (Cicchetti & Rogosch, 2001a, 2001b), maltreated and nonmaltreated children did not differ in their average level of morning cortisol, $t(313) = 1.60$, $p = .11$. Furthermore, no significant differences were found for the PA/SA, PN/EM, and nonmaltreated groups, $F(2, 312) = 1.41$, $p = .24$ (see Table 2). However, based on an interest in patterns of cortisol dysregulation (i.e., hypocortisolism, hypercortisolism) rather than solely on group mean levels, children were differentiated into three groups based on the sample's distribution of average morning cortisol scores: low morning cortisol (≤ -1 *SD*), medium morning cortisol (> -1 *SD* and $< +1$ *SD*), and high morning cortisol ($\geq +1$ *SD*). The proportion of children in the three cortisol groups differed between maltreated and nonmaltreated children, $\chi^2(2, N = 315) = 6.59$, $p = .04$. Group contrasts revealed that more maltreated children (19.7%) were in the low cortisol group compared to nonmaltreated children (10.4%), $\chi^2(1, N = 315) = 5.43$, $p = .02$, whereas the proportion in the high morning cortisol group did not differ between maltreated (14.8%) and nonmaltreated children (12.1%), $\chi^2(1, N = 315) = 0.47$, $p = .49$.

Maltreatment Subtypes, Cortisol Dysregulation, and Memory Performance

Next, a series of analyses of covariance (ANCOVAs) was conducted to examine maltreatment subtype groups and the three-level grouping of morning cortisol in relation to differences in memory processes, as indicated by standard scores from the CVLT–C, including short-delay recall, long-delay recall, recognition memory, false positive recognition memory, and the discriminability index. Subtype group means are presented in Table 2. Children's age and PPVT–III scores were used as covariates in all analyses. Initially, general memory processes, including short- and long-delay recall and recognition memory were examined. ANCOVAs for these variables did not result in any significant main or interactive effects (see Table 3).

In contrast, significant effects were obtained for false positive recognition memory, as shown in Table 3. In the ANCOVA, a significant effect was obtained for cortisol level, $F(2, 302) = 5.13$, $p = .01$; however, this effect was clarified by a significant interaction between maltreatment subtype and cortisol level, $F(4, 302) = 2.45$, $p = .05$. Figure 1 depicts the interactive effect. To probe the interaction effect, separate ANCOVAs were conducted within each of the maltreatment subtype groups to examine the relation of cortisol level to false recognition memory. The effect of cortisol level was not significant in the analysis for nonmaltreated children, $F(2, 167) = 1.38$, $p = .46$, or for the PA/SA group, $F(2, 55) = 1.97$, $p = .24$. However, a significant effect was obtained for the PN/EM group, $F(2, 76) = 9.01$, $p < .001$. Post hoc Tukey tests indicated that within the PN/EM group of children, the low-cortisol group had significantly higher false recognition memory scores than the average- and high-cortisol groups.

Table 2
Morning Cortisol and California Verbal Learning Test–Children (CVLT–C) Standard Scores for Maltreatment Subtype Groups

	Nonmaltreated	PN/EM	PA/SA
	M (*SD*)	*M* (*SD*)	*M* (*SD*)
Morning cortisol Z score	0.07 (0.98)	−0.14 (0.82)	−0.05 (1.27)
CVLT–C standard scores			
Short-delay free recall	−0.05 (0.90)	0.12 (0.91)	−0.05 (1.30)
Long-delay free recall	−0.59 (1.07)	−0.77 (1.15)	−0.64 (1.19)
Recognition memory	−0.23 (1.04)	−0.38 (1.29)	−0.20 (1.13)
False positive recognition	−0.07 (1.21)	0.01 (0.92)	0.27 (1.24)
Discriminability index	−0.24 (1.41)	−0.37 (1.16)	−0.55 (1.43)

Note. PN/EM = physical neglect and/or emotional maltreatment only; PA/SA = physical abuse and/or sexual abuse.

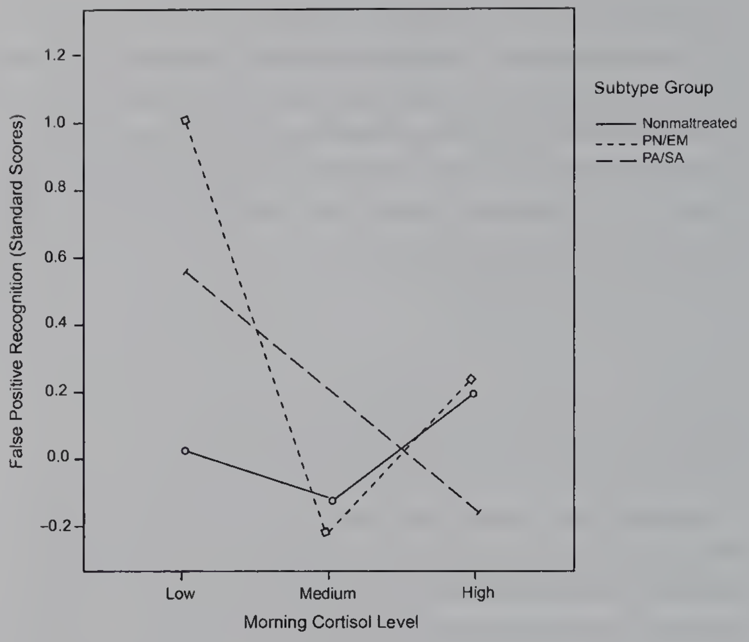

Figure 1. Interaction of maltreatment subtype group and level of morning cortisol for California Verbal Learning Test–Children false recognition memory.
Note. PN/EM = physical neglect and/or emotional maltreatment only; PA/SA = physical abuse and/or sexual abuse.

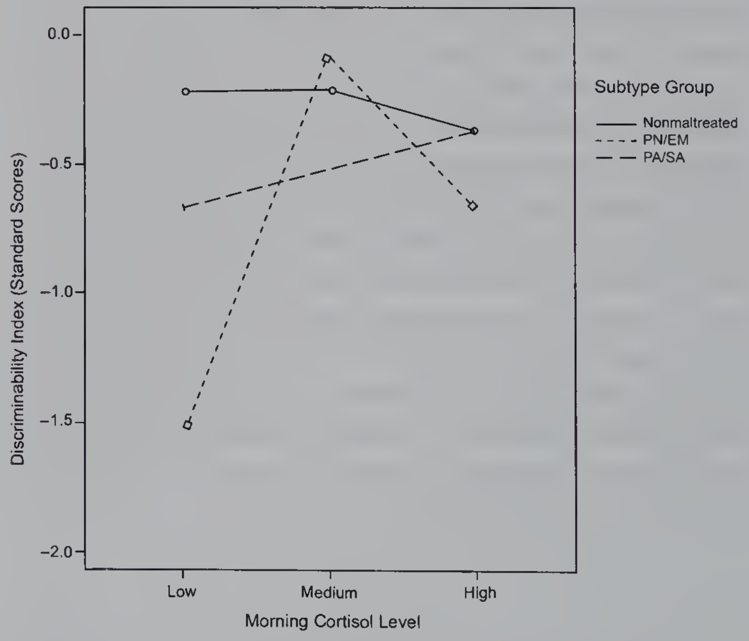

Figure 2. Interaction of maltreatment subtype group and level of morning cortisol for the California Verbal Learning Test–Children discriminability index.
Note. PN/EM = physical neglect and/or emotional maltreatment only; PA/SA = physical abuse and/or sexual abuse.

The discriminability index, which measures a child's ability to distinguish between target words and distractors, taking into account a child's recognition memory ability in relation to the rate of false positives, also was evaluated. False recognition memory and the discriminability index were correlated ($r = .49$, $p < .001$). The results from the ANCOVA for the discriminability index mirrored those observed for false recognition memory. The effect of cortisol levels was significant, $F(2, 302) = 3.16$, $p = .04$, and a marginally significant interaction effect between maltreatment subtype group and cortisol level was observed, $F(4, 302) = 2.28$, $p = .06$. This interaction is depicted in Figure 2. The interaction effect was probed by examining the effect of cortisol level on the discriminability index within each of the maltreatment subtype groups. No significant effect of cortisol level was found in the nonmaltreated group, $F(2, 167) = 0.10$, $p = .91$, or the PA/SA group, $F(2, 55) = 0.14$, $p = .87$, whereas a significant interaction was obtained for the PN/EM group, $F(2, 76) = 11.18$, $p < .001$. Post hoc Tukey tests indicated that among the PN/EM children, those with low morning cortisol group had significantly lower discriminability scores than children with medium level morning cortisol.

Additionally, the potential for retrieval and encoding deficits to influence these findings was evaluated. The overall rates of deficits in retrieval (10.4%) and in encoding (8.2%) in the sample were low. No significant differences between subtype groups were obtained for retrieval deficits, $\chi^2(2, N = 317) = 0.59$, $p = .74$, or for encoding deficits, $\chi^2(2, N = 317) = 1.18$, $p = .55$. Similarly, the cortisol groups also were not differentiated by the rate of retrieval deficits, $\chi^2(2, N = 317) = 0.87$, $p = .65$, or encoding deficits, $\chi^2(2, N = 317) = 0.28$, $p = .87$. Thus, retrieval and encoding deficits did not appear to be unique to particular subtype or cortisol level groups.

The differentiation in memory performance between the PA/SA and PN/EM groups was examined in further detail to determine if other aspects of child maltreatment would better explain the interaction effects of level of morning cortisol and subtype. Specifically, rather than subtype, various maltreatment features, including early onset of maltreatment in infancy and/or toddlerhood, chronicity based on number of developmental periods of maltreatment occurrence, recency of maltreatment, and the number of subtypes of maltreatment experienced were examined in the same ANCOVAs as utilized earlier. None of the interaction effects of the various maltreatment features and level of morning cortisol was significant, indicating that the subtype interactive effects provided the greatest explanatory power.

The Influence of Dissociative Symptomatology

The influence of dissociative symptomatology on the findings also was examined. Initially, an ANOVA was conducted to examine potential differences in dissociation scores based on cortisol levels and subtype group. Neither the main effect of cortisol level, $F(2, 303) = 0.42$, $p = .66$, nor the interaction of subtype group and cortisol level, $F(4, 303) = 0.79$, $p = .53$, was significant. However, significant subtype differences were found, $F(2, 303) = 7.37$, $p < .001$. Tukey post hoc tests indicated that children in both the PA/SA group ($M = 3.53$, $SD = 3.05$) and the PN/EM group ($M = 2.93$, $SD = 2.99$) had significantly higher dissociation scores on average than the nonmaltreated group ($M = 1.63$, $SD = 1.94$).

Next, given an interest in the effects of high levels of dissociative symptoms, children with dissociation symptoms > +1 *SD* were categorized into a high-dissociation group ($n = 51$), and all remaining children were categorized into a low-dissociation group ($n = 260$). The dissociation level factor was then used in subsequent ANCOVAs along with subtype group to predict memory performance, with age and PPVT–R standard scores as covariates. The main and interaction effects for these analyses were all nonsignificant for short-term recall, long-term recall, and recognition memory. In contrast, findings emerged for false recognition memory and discriminability. For false recognition memory, a main effect was found for dissociation level, $F(1, 311) = 4.37$, $p = .04$. However, this main effect was qualified by a significant interaction effect of dissociation level and subtype group, $F(2, 311) = 4.16$, $p = .02$. To probe the interaction, follow-up analyses were conducted within each subtype group. Whereas no significant differences in false recognition were observed between children with high and low dissociation levels in the PN/EM, $F(1, 75) = 1.53$, $p = .22$, or the PA/SA, $F(1, 56) = 1.50$, $p = .23$, groups, among the nonmaltreated group, children with high levels of dissociative symptoms had higher false recognition scores ($M = 0.90$, $SD = 1.66$) than those with low levels of dissociation ($M = -0.17$, $SD = 1.11$), $F(1, 168) = 8.91$, $p = .003$. Similar effects were found for discriminability, with a significant effect for the interaction of dissociation level and subtype group, $F(2, 303) = 3.29$, $p = .04$. Again, no differences were found within the PN/EM or PA/SA based on dissociation level, whereas among nonmaltreated children, those with high dissociation had poorer discriminability scores ($M = -1.20$, $SD = 1.89$) than those with low dissociation scores ($M = -0.13$, $SD = 1.31$), $F(1, 168) = 6.27$, $p = .04$. Finally, whether high dissociation was related to greater likelihood of retrieval or encoding deficits was examined; both chi-square tests were nonsignificant, *ps* > .80. Further analyses examining subtype, dissociation level, and cortisol group were not feasible given restrictions in cell sizes. Overall, the findings suggest that dissociation contributes to higher inaccurate memory among nonmaltreated children but does not influence false recognition or discriminability among PN/EM or PA/SA children. Thus, dissociation does not account for the attenuated memory performance of PN/EM children with low cortisol.

Discussion

Consistent with the extant literature, the findings from this investigation reveal that the experience of child maltreatment per se does not appear to adversely affect, nor does it enhance, basic memory for nontraumatic material (Howe, Cicchetti, et al., 2006; Howe, Toth, et al., 2006). Specifically, in accord with our hypotheses, the basic recall and recognition memory abilities of maltreated children did not differ from that of the nonmaltreated comparison children. Likewise, an examination of the rate of deficits in encoding and retrieval memory processes revealed no between group differences. Conversely, when examining HPA-axis functioning and memory, some interesting differences between maltreated and nonmaltreated comparison children do begin to emerge. As anticipated, differences were not found in the average morning basal cortisol of maltreated and nonmaltreated children. Notably, however, when different levels of cortisol regulation were examined, more maltreated children exhibited lower levels of basal cortisol than did nonmaltreated children.

Our hypothesis that low morning cortisol would result in increased false recognition memory in maltreated children was supported; however, our hypothesis that maltreated children who exhibited high morning cortisol levels would display increases in false recognition memory was not confirmed. More specifically, in the present study the expectation that the subgroup of maltreated children with low cortisol who had experienced PN/EM would exhibit increased false recognition memory and poorer discriminability was confirmed. These results are in keeping with those reported in two prior investigations of false memory in maltreated children (Eisen et al., 2007; Valentino et al., 2008b). In both of these investigations, children who had experienced physical neglect and often co-occurring emotional maltreatment evinced increased levels of memory inaccuracy compared to children who experienced physical abuse and/or sexual abuse.

Furthermore, an in-depth examination of additional MCS variables that could have influenced the results obtained included an investigation of the potential contribution of age of onset of maltreatment, the number of developmental periods during which a child experienced maltreatment, the recency of maltreatment, and the distinct number of subtypes of maltreatment that occurred. None of these factors were found to interact significantly with morning levels of cortisol. Thus, the significant interaction effect of physical neglect and/or emotional maltreatment and low levels of morning cortisol resulted in the clearest identification of a subgroup of maltreated children with elevated recognition inaccuracy.

To the best of our knowledge, the finding that low basal levels of cortisol are associated with impairments in false recognition memory in neglected and/or emotionally maltreated children is the first demonstration that a form of cortisol dysregulation known as hypocortisolism can exert negative effects on memory. Conversely, we did not find an association between high basal levels of cortisol and increased false recognition memory. The absence of differences for high basal cortisol may be related to the co-occurrence of psychopathology, specifically, dissociation. The only previous investigation to examine memory processes and cortisol in maltreated children and adolescents (Eisen et al., 2007) found that among children with high levels of dissociative symptomatology, high cortisol reactivity to a stressful medical examination was associated with memory impairment (i.e., increased suggestibility); however, for children with low levels of dissociation, high cortisol reactivity was not found to relate to suggestibility of memory. Thus, it appears that high levels of dissociation moderated the relation between cortisol reactivity and suggestibility. Unfortunately, due to sample size restrictions, the Eisen et al. (2007) study could not examine the possible effects of maltreatment subtype on cortisol reactivity.

In the current investigation, maltreated children in the physically and/or sexually abused and the physically neglected and/or emotionally maltreated groups had greater levels of dissociative symptoms than did the nonmaltreated comparison children. Cortisol level alone or in interaction with subtype did not predict dissociation symptoms. Similar to the results obtained by Eisen et al. (2007), we found that high dissociation was related to higher false recognition memory; however, in contrast, and contrary to our expectations, in our investigation these results held true only for the nonmaltreated comparison group of children with high dissociative symptoms. We did not find any relation between high dissociation and higher false recognition memory for the physically and/or sexually abused or the physically neglected and/or emotionally maltreated groups. It should be kept in mind that the

Eisen et al. study focused on cortisol reactivity (and not basal levels, as we did) and assessed an affectively laden form of memory (suggestibility in response to a medical exam as opposed to inaccuracies in basic recognition memory).

Our findings suggest that there may be two different risk profiles associated with false recognition memory. For the subgroup of nonmaltreated children, increased levels of dissociative symptoms appear to be the contributor to false recognition memory. In contrast, increased dissociative symptomatology was not related to false recognition memory in the physically neglected and/or emotionally maltreated subgroup of children; rather, low levels of basal cortisol were found to be associated with false recognition memory. Among children in the physically and/or sexually abused group, there does not appear to be a risk profile for recognition memory inaccuracy. Specifically, neither increased dissociation, nor cortisol level were associated with false recognition memory for these children.

Because the HPA axis has been demonstrated to down-regulate in response to chronic stressors, the presence of hypocortisolism suggests that HPA-axis dysregulation has been operating for a prolonged period of time. Just as has been found in empirical studies of hypercortisolism and memory (McEwen & Stellar, 1993; Sapolsky, 1996), the HPA-axis dysregulation characteristic of hypocortisolism also may be related to neurobiological sequelae and memory impairments.

Neuroimaging studies conducted with maltreated individuals have revealed that the hippocampus, the major brain structure that subserves memory, evinces structural decreases in volume among adults (Bremner et al., 2003). However, cross-sectional and short-term longitudinal studies of maltreated children and adolescents with PTSD have not found evidence of structural hippocampal impairments (DeBellis, 2001, 2005). Although stress-induced hypercortisolism has often been invoked as a potential neurobiological mechanism underlying the development of hippocampal damage, it is conceivable that hypocortisolism also may be a likely indicator of hippocampal damage given that the HPA axis of individuals with hypercortisolism over time would tend to down-regulate in response to prolonged hyperactivation.

It is instructive to consider why it was the subgroup of physically neglected and/or emotionally maltreated children with low levels of cortisol who exhibited the increased false recognition memory impairments, whereas the physically and/or sexually abused children with low levels of cortisol, who also had levels of neglect and emotional maltreatment comparable to the PN/EM group, did not reveal increases in false recognition memory. It is possible that the more distinct incidents of trauma experienced by physically and/or sexually abused children may contribute to enhanced attention and greater vigilance to environmental stimuli. In turn, this hypervigilance may counteract the negative effects of hypocortisolism upon memory. The lack of predictability associated with when physical and/or sexual abuse occurs may engender hypervigilance to aggression in these children, even when abusive events are not taking place (Pollak, Cicchetti, Klorman, & Brumaghim, 1997; Rieder & Cicchetti, 1989; Teisl & Cicchetti, 2008). The prior experience of anger and trauma may impel physically and sexually abused children to engage in a more careful monitoring of each context they experience (cf. Pollak & Kistler, 2002; Pollak, Vardi, Putzer-Bechner, & Curtin, 2005; Shackman, Shackman, & Pollak, 2007). Moreover, the chronic nature of neglect most likely involves general rather than discrete memories. Although further investigation is necessary, it may be that a memory system organized around overgeneral memories is more prone to impaired memory performance in the context of hypocortisolism.

The fact that maltreated children who have not experienced physical or sexual abuse exhibit memory impairments in conjunction with hypocortisolism is quite interesting. In fact, various subgroups of maltreated children display increases in false recognition and recall memory under mother-referent and self-referent conditions (Valentino et al., 2008a, 2008b). Why have differences not been found in other forms of basic memory? Why has hypercortisolism not resulted in memory difficulties in maltreated children? Alternatively, does hypercortisolism initiate the pathway from hyper- to hypocortisolism to structural neurobiological changes in the hippocampus that alter basic memory processes?

In order to address these challenging questions in a manner that is commensurate with the complexity of the issues noted, future investigations must be conducted that strive to identify other factors that may exert mediating or moderating effects on false recall and recognition memory. It will be important to conduct prospective longitudinal investigations that repeatedly assess HPA-axis functioning and various forms of basic memory, utilizing diverse memory paradigms. The incorporation of molecular genetic techniques into these studies also could help to elucidate, for example, how variants of glucocorticoid receptor genes and corticotrophin receptor hormone genes, and variations in catechol-o-methyl-transferase genes may serve as moderators of the relation among maltreatment, HPA-axis functioning, and memory. Ideally, subgroups of maltreated children who have either hyper- or hypocortisolism should also receive periodic structural and functional neuroimaging assessments. Such multiple levels of analysis research programs have the potential to provide answers to key questions that the field of memory and trauma must address.

The findings of this investigation contribute to the extant literature by highlighting the interplay between neglect and/or emotional maltreatment and hypocortisolism in relation to false recognition memory. In view of the current findings related to subtype of maltreatment, it is important to note that physically neglected and emotionally maltreated children have been accorded less attention than physically and sexually abused children in research conducted to date on basic memory processes in maltreated children. Although the emphasis on investigating memory in physically and sexually abused children is understandable given that these forms of maltreatment are particularly heinous forms of child maltreatment, it was the physically neglected and emotionally maltreated children who exhibited the impairments in false recognition memory. Thus, future research on memory processes in maltreated children should include groups of physically neglected and emotionally maltreated children (cf. Eisen et al., 2007; Valentino et al., 2008a, 2008b).

Similarly, forensic work typically is more focused on physical and sexual abuse cases. These children, even the subgroup with low cortisol, do not appear to have a greater likelihood of false recognition memory; however, the less studied physically neglected and emotionally maltreated children do show evidence of increases in false recognition memory. The findings of the current investigation urge caution in prematurely assuming that the memories of neglected children are less affected than are those of children who have experienced physical or sexual abuse.

It is important to acknowledge that the findings of the current investigation may not generalize to maltreated children who do not come to the attention of child protective agencies. A potential limitation of the current study is the difficulty in being able to identify sufficient numbers of children who were abused but not neglected and/or emotionally maltreated in order to have distinct group comparisons. However, the co-occurrence of these forms of maltreatment is typical in this population, and an exclusive focus on children who were only abused would result in poor generalizability to the larger maltreated population. Nevertheless, it does not seem likely that the memory performance of the atypical group of children who are exclusively physically and/or sexually abused would be markedly different from those who also have had neglect and/or emotional maltreatment experiences.

The current investigation also possesses implications for intervention. It is imperative that children who have been neglected and/or emotionally maltreated be afforded access to services commensurate with those more commonly provided to children who have been physically or sexually abused. Because neglected and/or emotionally maltreated children may evidence perturbations in memory associated with their experiences, the provision of narrative therapies that assist them in developing a cohesive life story in the context of neglect and emotional maltreatment may be particularly useful (Fivush, Bohanek, Robertson, & Duke, 2004). Such therapeutic approaches ultimately may prevent the coalescence of the negative self-representations frequently associated with experiences of maltreatment (Toth, Cicchetti, Macfie, Rogosch, & Maughan, 2000; Toth, Maughan, Manly, Spagnola, & Cicchetti, 2002).

The Contributions of Numerosity and Domain-General Abilities to School Readiness

Lynn S. Fuchs
Vanderbilt University

David C. Geary
University of Missouri

Donald L. Compton, Douglas Fuchs, Carol L. Hamlett, and Joan D. Bryant
Vanderbilt University

Contributions of domain-general and domain-specific numerical competencies were assessed on first graders' number combination skill (NC) and word-problem skill (WP). Students ($n = 205$) between 5 and 7 years of age were assessed on 2 aspects of numerosity, 8 domain-general abilities, NC, and WP. Both aspects of numerosity predicted NC when controlling for domain-general abilities, but domain-general abilities did not account for significant additional variance. By contrast, when controlling for domain-general abilities in predicting WP, only precise representation of small quantities was uniquely predictive, and domain-general measures accounted for significant additional variance; central executive component of working memory and concept formation were uniquely predictive. Results suggest that development of NC and WP depends on different constellations of numerical versus more general cognitive abilities.

In an analysis of six large-scale longitudinal studies, Duncan, Dowsett, Classens, et al. (2008) demonstrated that mathematical competence at school entry predicts mathematics achievement throughout the elementary school years, above and beyond general cognitive ability, classroom attention, social skills, or socioeconomic background. In fact, performance on early mathematical achievement tests was by far the single best predictor of later mathematics achievement. They suggested "it may be beneficial to add domain-specific early skills to the definition of school readiness" (Duncan et al., 2008, p. 1429), but their analysis did not allow for the assessment of which specific mathematical competencies may be the best target for such programs. Candidates center on children's early number sense, including the ability to quickly apprehend the quantities of small sets of items, use counting to determine quantity, estimate the value of large quantities, and intuitively understand the effects of addition and subtraction on quantity (National Mathematics Advisory Panel, 2008).

At the same time, Duncan et al. (2008) showed that classroom attention, a domain-general factor, also predicts later mathematics achievement, above and beyond early mathematical competence. Other studies have revealed that general cognitive ability is also a strong predictor of achievement across academic domains (e.g., Walberg, 1984). General cognitive ability includes working memory capacity, speed of information processing, and logical reasoning (Embretson, 1995; Engle, Tuholski, Laughlin, & Conway, 1999; Kail, 1991), although the relative importance of these domain-general abilities is debated (e.g., Ackerman, Beier, & Boyle, 2005).

In the present study, we focused on the relation between two measures of children's early number sense as well as domain-general cognitive and attentional measures with performance on two critical mathematical abilities: fluency in solving arithmetic problems (e.g., $5 + 7 = 12$; $9 - 5 = 4$), which are sometimes referred to as number combinations (NCs; Baroody, 1985), and simple word problems

(WPs) that require solution of NCs. By assessing competencies in NC and WP, rather than using broad achievement measures, we explored the relative importance of domain-specific versus domain-general abilities to each of these core aspects of children's early mathematical learning. If Duncan et al. (2008) are correct, then measures of children's number sense should predict NC and WP competence, with domain-general measures accounting for relatively little additional variance. Such findings would help to more firmly establish links between children's informal (before schooling) number sense and their emerging competencies in school-taught mathematics and provide direction for the foci of school readiness programs.

The Domain-General Mechanisms

Of the domain-general mechanisms, working memory, classroom attention, and speed of processing have all been shown to predict NC performance (e.g., Bull & Johnston, 1997; Fuchs et al., 2005; Hitch & McAuley, 1991), but none of the studies assessed these potential mechanisms simultaneously with each other and with domain-specific measures of number sense. Moreover, working memory itself constitutes multiple subcompetencies that may influence NC development in different ways.

At the least, working memory comprises an attention-driven central executive, which controls the representation and manipulation of information in two subsystems that provide short-term storage (Baddeley, 1986). The phonological loop stores auditory or phonological information; the visuospatial sketchpad stores spatial and visual information such as shapes and colors or the location or speed of objects in space. Correlational studies suggest that the central executive is critical for NC development (e.g., Geary, Hoard, Byrd-Craven, Nugent, & Numtee, 2007; Swanson & Sachse-Lee, 2001), but the subcomponents of the central executive contributing to this performance, including attentional and inhibitory control, are not well understood. Attentional control may be necessary to maintain the simultaneous activation of problem stems and answers in working memory while counting solutions; inhibitory control may be needed to prevent irrelevant associations from intruding into working memory during problem solving (Barrouillet, Fayol, & Lathuliére, 1997; Engle et al., 1999).

The phonological loop may contribute to the establishment of NCs in long-term memory, because children must encode and maintain accurate phonological representations of problem stems and answers in working memory as they count to solve problems (e.g., Logie & Baddeley, 1987). Evidence on the link between phonological processing and NC skill is, however, inconsistent (e.g., Fuchs et al., 2005; Hecht, Torgesen, Wagner, & Rashotte, 2001; Swanson & Beebe-Frankenberger, 2004). Attentive behavior in the classroom can also influence NC skill (Fuchs et al., 2005; Fuchs et al., 2006), but the relation between this type of attention and the attentional and inhibitory control components of the central executive are not well understood.

The search for the mechanisms underlying NC skill is further complicated by the relation between working memory and speed of processing (the efficiency with which simple tasks are executed; Case, 1985). Bull and Johnston (1997) found that behavioral measurement of processing speed was the best predictor of NC skill among 7-year-olds, subsuming all the variance accounted for by long- and short-term memory, even with reading skill controlled. Hecht et al. (2001) provided corroborating data while controlling for oral vocabulary, and profile analysis (Fuchs, Fuchs, Stuebing, et al., 2008) showed that a behavioral measure of processing speed distinguishes third graders with specific NC deficits from those with WP deficits. However, it is not known whether individual differences in working memory are driven by more fundamental differences in speed of processing (Kail, 1991) or whether the attentional focus associated with the central executive speeds information processing (Engle et al., 1999).

Working memory is also related to WP performance but the contributions of the different components of working memory are not fully understood (e.g., Hitch & McAuley, 1991; Swanson & Sachse-Lee, 2001). Moreover, as noted, performance on working memory measures is correlated with logical reasoning, but processes are distinct to each (Embretson, 1995). General reasoning ability predicts third graders' WP performance even after controlling for working memory (Fuchs et al., 2005, 2006; Swanson & Sachse-Lee, 2001). Finally, we must consider oral language comprehension as a contributor to WP skill, above and beyond the contributions of the phonological loop. Jordan, Levine, and Huttenlocher (1995) demonstrated that kindergarten and first-grade children with oral language impairment perform lower than unimpaired peers on WPs. Fuchs et al. (2006) showed the relation between language and WP skill at third grade while controlling for a variety of other variables, and profile analysis (Fuchs, Fuchs, Stuebing, et al., 2008) revealed that oral language comprehension distinguishes third graders with WP deficits versus those with specific calculation deficits.

The Domain-Specific Mechanisms

In addition to general cognitive abilities, which apply across academic domains, children may have specialized numerical representations and competence in numerical processing (e.g., Baroody, Bajwa, & Eiland, 2009; Feigenson, Dehaene, & Spelke, 2004). Cognitive (Gilmore, McCarthy, & Spelke, 2007), neuropsychological (Domahs & Delazier, 2005), and brain-imaging (Cantlon, Platt, & Brannon, 2009) studies indicate that number sense mechanisms support children's early learning of school-taught mathematics. As per Feigenson et al. (2004), two core systems, one for exact representation of small quantities and one for approximating larger quantities, may be involved in representing numerical value, although controversy exists about whether these systems are supported by distinct cognitive and brain mechanisms (e.g., Cantlon et al., 2009; Gallistel & Gelman, 1992; Mix, Huttenlocher, & Levine, 2002; vanMarle & Wynn, 2009). Whether the underlying mechanisms are cognitively or neurally distinct, they are functionally so; people of any age can rapidly distinguish the quantities of sets of less than four objects but must count or approximate the values of larger sets and Arabic numerals.

The hypothesized first system supports analog representations of approximate numerical magnitudes (Gallistel & Gelman, 1992; Xu, 2003) and can be assessed based on children's placement of numerals on a number line (e.g., Siegler & Booth, 2004). Making placements on a number line, which are based on the use of this approximate magnitude system, results in a pattern that conforms to the natural logarithm (ln) of the numbers (Feigenson et al., 2004; Gallistel & Gelman, 1992; Siegler & Opfer, 2003). In other words, use of this representational system results in placements that are compressed for larger magnitudes such that the perceived distance between 52 and 53 is smaller than the perceived distance between 2 and 3. With schooling, children learn to make placements that conform to the mathematical number line; that is, their placements suggest they understand that the difference between two consecutive numbers is identical regardless of position on the line.

The second hypothesized system enables precise representations of small quantities, the fast apprehension of which is termed *subitizing* (Mandler & Shebo, 1982). With a verbal subitizing task, which involved name identity, Koontz and Berch (1996) asked third and fourth graders with and without a mathematical learning difficulty to determine whether combinations of Arabic numerals (e.g., 3–2), number sets (e.g., ■ ■–■ ■), or numerals and sets were the same (e.g., 2–■ ■) or different (e.g., 3–■ ■). Reaction times for children without mathematics difficulty indicated fast access to representations for quantities of two and three, regardless of whether the code was an Arabic numerical or number set. Children with mathematics difficulty showed fast access to numerosity representations for the quantity of two but appeared to rely on counting to determine quantities of three. Geary et al. (2007; Geary, Bailey, & Hoard, 2009) developed the Number Sets Test to assess related, basic numerical fluency. Children are asked to combine pairs or triplets of Arabic numerals (e.g., 3 4) or sets of objects (e.g., •• ■ ■ ■) and quickly determine if they match a target number (e.g., 5). Verbal subitizing can contribute to fluency if the quantity of small sets of objects is apprehended and then added together (e.g., •• ■ ■ ■ = 5; Geary & Lin, 1998). Children with mathematics difficulty perform poorly on this task compared to peers, independent of general cognitive ability, but performance may be mediated by visuospatial working memory (Geary et al., 2008).

Purpose of the Present Study

In the present study, we assessed the relative contributions of domain-general working memory, attentional, language, and reasoning abilities and domain-specific numerical competencies on individual differences in first graders' NC and WP performance. We had three goals. The first was to determine whether measures of the approximate and exact number representation systems directly affect NC skill when controlling for domain-general abilities. Evidence for one or the other numerosity measure would support Duncan et al.'s (2008) suggestion that domain-specific competence may be important for children's early mathematical learning. Such a finding would also provide much needed information on where to target early interventions for children at risk for poor outcomes in mathematics (e.g., Siegler & Ramani, 2008). Our second goal was to determine how much of the variance in domain-general abilities and numerosity variables represents unique versus shared variance in explaining NC skill. Finding that domain-general abilities uniquely account for much of the variance would suggest that children's early mathematics learning is supported by the same mechanisms that support learning in other domains; finding that the numerosity variables uniquely account for much of the variance would substantiate a domain-specific perspective. By contrast, finding that a substantial amount of the variance is shared would suggest the viability of a combined perspective. Our third goal was to address the same issues as in our first two goals but applied to WPs that require solutions to NCs. These analyses assess whether domain-general or domain-specific relations found for NCs generalize to mathematics content beyond NC skill.

Method

Participants

As part of a prospective 4-year study of the development of NC skill beginning in first grade, data for the present study were collected with the first-year sample at the first assessment wave, when we sampled children from 52 first-grade classrooms in nine Title 1 schools and two non-Title 1 schools (2–9 teachers per school) in a Southeastern metropolitan school district. From 898 students in these classrooms, we secured consent on 580 (64.6%), who were then screened for inclusion using a two-step process. Step 1 involved whole-class screening on the First-Grade Test of Computational Fluency and the First-Grade Test of Mathematics Concepts and Applications (Fuchs, Hamlett, & Fuchs, 1990; see Measures). Teachers first used scripts to administer two practice alternate forms of each measure. Prior to actual screening, teachers returned the unscored practice tests to project staff. Screening occurred with one additional alternate form of each measure. In Step 2, all students who were present on the day of whole-class screening (n = 507) were tested individually on measures of early reading: Rapid Letter Naming (Fuchs et al., 2001) and Word Identification Fluency (Fuchs, Fuchs, & Compton, 2004; see Measures). We indexed early reading for screening because evidence indicates that students with concurrent difficulty with mathematics and reading may experience more severe difficulty with NCs (e.g., Hanich, Jordan, Kaplan, & Dick, 2001).

Using mixture analysis that combined the four screening scores into a latent variable, we created high, average, and at-risk strata. We combined the high and average strata into a single "not-at-risk" group. We then applied the following exclusions. First, we excluded 73 students whose mathematics performance was inconsistent with their overall risk status (i.e., at-risk students with high mathematics scores and not-at-risk students with low mathematics scores). Second, we excluded 121 students whose teachers identified them as not speaking English. Third, we administered the two-subtest Wechsler Abbreviated Intelligence Scale (WASI; Wechsler, 1999) and excluded 7 students with standard scores below 80 on both subtests (i.e., our goal was not to study mental retardation).

From the remaining 306 students, we randomly sampled 240 students, purposely stratifying by the at-risk and not-at-risk strata and ensuring that no more than 8 students came from the same classroom. The present sample comprises the 205 students on whom we had complete data on the study variables. These students had mean standard scores in the normal range on the Reading subtest of the Wide Range Achievement Test–3 (WRAT; Wilkinson, 1993), 105.12 (SD = 15.35); WRAT-Arithmetic, 96.63 (SD = 14.63); KeyMath–Revised (Connolly, 1998)–Numeration, 102.80 (SD = 11.29); KeyMath–Revised–Addition, 99.90 (SD = 10.46); KeyMath–Revised–Subtraction, 97.30 (SD = 11.97); and WASI IQ, 92.70 (SD = 13.31). Of the 205 participants, 109 (53.2%) were boys; 161 (78.5%) received subsidized lunch. Among the students, 112 (54.6%) were African American, 48 (23.4%) were European American, 24 (11.7%) were Hispanic, and 21 (10.2%) were other. Students with a school-identified disability comprised 4.8% of the sample.

Screening Measures to Constitute a Representative Sample

Mathematics screeners. Because these measures were used to screen overall mathematics competence, they included problems with a range of difficulty to be sensitive to the skills of low, average, and high performers.

The First-Grade Test of Computational Fluency (Fuchs et al., 1990) is a one-page test displaying 25 items that sample the range of problems typically found in the first-grade computation curriculum: adding two single-digit numbers (9 items), subtracting two single-digit numbers (10 items), adding three single-digit numbers (2 items), adding two 2-digit numbers without regrouping (2 items), and subtracting a one-digit number from a two-digit number (2 items). Students have 2 min to complete as many items as possible. The score is the number of digits correct (starting from the right, credit is awarded if the correct numeral is in the correct place so that 38 + 26 = 514 would earn one digit correct to reflect incorrect regrouping). Staff entered responses into a computerized program on an item-by-item basis, with 15% of tests reentered by an independent scorer. Data-entry agreement was 99.8% (i.e., number of agreements divided by number of agreement plus disagreement). Coefficient alpha was .97.

The First-Grade Test of Mathematics Concepts and Applications (Fuchs et al., 1990) is a three-page test with 25 items sampling the typical first-grade concepts and applications curriculum (i.e., numeration, concepts, geometry, measurement, applied computation, money, charts, graphs, and WPs). For example, items require students to count arrays of items, write the number after, identify smaller/larger quantities, read clocks, and identify operators within number sentences. The tester reads the words in each item aloud. For 20 items, students have 15 s to respond; for the remaining 5 items, students have 30 s. The score is the number of correct answers. Staff entered responses into a computerized program on an item-by-item basis, with 15% reentered by an independent scorer. Data-entry agreement was 98.8%. Coefficient alpha was .93.

Reading. With Rapid Letter Naming (Fuchs et al., 2001), students are shown a page with 52 letters (26 letters in upper and lowercase) displayed in random order and have 1 min to say letter names. The score is the number of correct letters. If the child finishes before 1 min, the score is prorated. Two-week stability is .94 (Fuchs et al., 2001). With Word Identification Fluency (Fuchs et al., 2004), students have 1 min to read a list of 50 words randomly sampled from a pool of 100 high-frequency preprimer, primer, and first-grade words. If a student completes reading before 1 min, the score is prorated. We administered two alternate forms and averaged the scores. Alternate-form reliability/stability is .97, and correlations with fall and spring Woodcock Reading Mastery Test–Word Identification (Woodcock, 1998) are .77–.82.

Intelligence. Wechsler Abbreviated Intelligence Scale (Wechsler, 1999) measures generalized cognitive ability with Vocabulary and Matrix Reasoning (see description next). Subtest scores are combined to yield an Estimated Full Scale IQ score. Internal consistency reliability exceeds .92.

Domain-General Predictor Measures

Language. We used two tests of language. Woodcock Diagnostic Reading Battery (WDRB)–Listening Comprehension (Woodcock, 1997) measures the ability to understand sentences or passages. With 38 items, students supply the word missing at the end of each sentence or passage. The test begins with simple verbal analogies and associations and progresses to comprehension involving the ability to discern implications. Testing is discontinued after six consecutive errors. The score is the number of correct responses. Internal consistency reliability is .80 at ages 5–18; the correlation with the Woodcock-Johnson Psycho-Educational Battery–Revised (WJ–R) is .73. WASI Vocabulary (Wechsler, 1999) measures expressive vocabulary, verbal knowledge, and foundation of information with 42 items. The first four items present pictures; the student identifies the object in the picture. For the remaining items, the tester says a word that the student defines. Responses are awarded a score of 0, 1, or 2 depending on quality. Testing is discontinued after five consecutive scores of 0. The score is the total number of points. As reported by Zhu (1999), split-half reliability is .86–.87 at ages 6–7; the correlation with the WISC–III Full-Scale IQ is .72.

Concept formation. Woodcock-Johnson Psycho-Educational Battery–Revised (WJ–III) Concept Formation (Woodcock, McGrew, & Mather, 2001) asks students to identify the rules for concepts when shown illustrations of instances and noninstances of the concept. Examinees earn credit by correctly identifying the rule that governs each concept. Cut-off points determine the ceiling. The score is the number of correct responses. As reported by the test developer, internal consistency reliability is .93.

Nonverbal problem solving. Wechsler Abbreviated Intelligence Scale Matrix Reasoning (Wechsler, 1999) measures nonverbal reasoning with four types of tasks: pattern completion, classification, analogy, and serial reasoning. The child looks at a matrix from which a section is missing and completes it by saying the number of or pointing to one of five response options. Examinees earn points by identifying the correct missing piece of the matrix. Testing is discontinued after four errors on five consecutive items or four consecutive errors. The score is the number of correct responses. Internal consistency reliability is .94; the correlation with the WISC–III Full-Scale IQ is .66.

Attentive behavior. The SWAN is an 18-item teacher rating scale (Swanson et al., 2004), sampling items from the *Diagnostic and Statistical Manual of Mental Disorders–IV* (American Psychiatric Association, 1994) criteria for Attention Deficit/Hyperactivity Disorder for inattention (largely distractibility; items 1–9) and hyperactivity/impulsivity (items 10–18). Items are rated as 1 = *far below*, 2 = *below*, 3 = *slightly below*, 4 = *average*, 5 = *slightly above*, 6 = *above*, 7 = *far above*. We report data for the attentive behavior subscale as the average rating across the nine relevant items. We selected this subscale to operationalize attentive behavior, or the ability to maintain focus of attention. The SWAN correlates well with other dimensional assessments of behavior related to attention (http://www.adhd.net). Coefficient alpha in the present study was .97.

Working memory. The Working Memory Test Battery for Children (WMTB–C; Pickering & Gathercole, 2001) comprises nine subtests that assess the central executive, phonological loop, and visuospatial sketchpad. Each subtest has six items at span levels ranging from 1–6 to 1–9. Passing four items at a level moves the child to the next level. At each span level, the number of items to be remembered increases by one. Failing three items terminates the subtest. The order of subtests is designed to avoid overtaxing any one component area of working memory and is generally arranged from easiest to hardest: Digit Recall, Word List Matching, Word List Recall, Nonword List Recall, Block Recall, Mazes Memory, Listening Recall, Counting Recall, and Backward Digit Recall. Each subtest generates a span score and a trials correct score. From these, standard scores are derived for the three component areas.

The *central executive* is assessed with three dual-task items. For Listening Recall, the child determines if a sentence is true or false and then recalls the last word in a series of sentences. For Counting Recall, the child counts a set of 4, 5, 6, or 7 dots on a card and then recalls the number of counted dots at the end of a series of cards. Backward Digit Recall is a standard format backward digit span.

The *phonological loop* comprises Digit Recall, Word List Recall, and Nonword List Recall, which are standard span tasks. The child repeats stimuli spoken by the tester in the same order. In Word List Matching, the tester presents a series of words, beginning with two words and adding one word at each level. The same words, but possibly in a different order, are then presented again, and the child determines if the second list is in the same order as the first list.

The *visuospatial sketchpad* comprises two tasks. Block Recall is another span task, but the stimuli consist of a board with nine raised blocks in what appears as a random arrangement. The blocks have numbers on one side that only the tester can see. The tester taps a block (or series of blocks), and the child duplicates the tapping in the same order. For Mazes Memory, the tester presents a maze with more than one solution and a picture of an identical maze with a path showing one solution. The picture is removed, and the child duplicates the path in the response booklet. At each level, the complexity of the maze increases.

Processing speed. Woodcock-Johnson Psycho-Educational Battery–Revised Visual Matching (Woodcock et al., 2001) asks examinees to locate and circle two identical numbers in rows of six numbers; examinees have 3 min to complete 60 rows and earn credit by correctly circling the matching numbers in each row. As reported by the test developer, internal consistency reliability is .91.

Domain-Specific Measures of Numerosity

We indexed numerosity with Number Line Estimation, which provides an assessment of the approximate magnitude system, and the Number Sets Test, which provides an assessment of precise representation of precise small quantities and the ability to mentally combine these representations (e.g., •• ■■■ = 5).

Approximate numerical magnitudes. Following Siegler and Booth (2004), Number Line Estimation asks students to estimate where numbers fall on a number line. Stimuli are twenty-four 25-cm number lines, displayed across the center of a standard computer screen. Each number line has a start point of 0 and an endpoint of 100 with a target number printed approximately 5 cm above it in a large font (72 pt). Target numbers are 3, 4, 6, 8, 12, 17, 21, 23, 25, 29, 33, 39, 43, 48, 52, 57, 61, 64, 72, 79, 81, 84, 90, and 96. Stimuli are presented in random order for each child. The tester first explains a number line that includes the 0 and 100 endpoints and is marked in increments of 10. After the tester judges that the child recognizes the concept, a number line containing only the endpoints 0 and 100 is presented, and the child points to where 50 should go. A model number line with the endpoints and the location of 50 marked is then presented, and the child compares his or her response to the model. The tester explains how "the number 50 is half of 100, so we put it halfway in between 0 and 100 on the number line." Next, the tester teaches the child to use the arrow keys to place a red pointer on the line where 50 should fall on the computer screen. Then, the measure is administered. For each item, the tester says, "If this is zero (pointing) and this is 100 (pointing), where would you put *N*?" There is no time constraint. We used the absolute value of the difference between the correct placement and the child's placement (i.e., estimation of accuracy), averaged across trials, which the computer automatically calculates. This estimation accuracy score correlates with mathematics achievement (Geary et al., 2007; Siegler & Booth, 2004), and as Siegler and Booth showed, the source of improvement in estimation accuracy is increasing linearity of estimates. Cronbach's alpha on this sample was .91.

Precise representation of small quantities. The Number Sets Test (Geary et al., 2009) assesses the speed and accuracy with which children understand and manipulate small, exact numerosities, while handling those quantities and their Arabic code. Two types of number-set stimuli are used: objects (circles, squares, diamonds, stars) in a 1/2 in. square and an Arabic numeral (18 pt font) in a 1/2 in. square. Stimuli are joined in domino-like rectangles. The two sides of the "domino" are objects–same objects or objects–different objects or Arabic numerals–Arabic numerals or objects–Arabic numerals. These dominos are presented in lines of 5 across a page. The last two lines of the page show 3 three-square dominos. Target sums (5 or 9) are shown in larger font (36 pt) at the top of the page; 5 and 9 were chosen because they represent smaller and larger values within the range of basic Arabic numerals (i.e., 1–9). The first page for each target sum contains objects–same objects and objects–different objects; the second page, objects–Arabic numerals and Arabic numerals–Arabic numerals. On each page, 18 items match the target, 12 are larger than the target, 6 are smaller than the target, and 6 contain 0 or an empty square. The tester begins by explaining two items matching a target sum of 4m then uses the target sum of 3 for practice; with four lines of two dominos, one is a match and one is not. The measure is then administered. The child is told to move across each line of the page from left to right without skipping any; to "circle any groups that can be put together to make the top number, 5 (9)," and to "work as fast as you can without making many mistakes." The child has 60 s per page for the target sum 5, 90 s per page for the target sum 9 (time limits chosen to avoid ceiling effects and to assess fluent recognition of quantities). Signal detection methods are applied to the number of hits and false alarms to generate a *d′* variable that represents the child's sensitivity to quantities (Geary et al., 2009; MacMillan, 2002). Children who correctly identify many target quantities and commit few false alarms have high *d′* scores. Children who have as many hits as false alarms have low *d′* scores, in which case the high number of correct items is due to the child's bias to respond, not sensitivity to quantity.

Mathematics Outcomes

Number combinations. Math Fact Fluency (Fuchs, Hamlett, & Powell, 2003) incorporates two subtests. Addition Fact Fluency comprises 25 addition fact problems with sums from 5 to 12 (2 items have an addend of 1; 1 item has an addend of 0). Subtraction Fact Fluency comprises 25 subtraction fact problems with subtrahends from 5 to 12 (1 item has a minuend of 1; 1 item has a minuend of 0). For each subtest, students have 1 min to write the answers. The score is the number of correct answers across both subtests. Percentage of agreement, calculated on 20% of protocols by two independent scorers, was 97.3. Coefficient alpha on this sample was .94.

Word problems. Following Jordan and Hanich (2000), Word Problems comprises 14 brief WPs involving change, combine, compare, and equalize relationships. The NCs embedded in the WPs are sums of 7, 8, or 9 or subtrahends of 6, 7, 8, or 9; there are no addends or minuends of 0 or 1; and answers to the subtraction problems range from 2 to 6. The tester reads each item aloud; students have 30 s to respond and can ask for rereading(s) as needed. The score is the number of correct answers. A second scorer independently rescored 20% of protocols, with agreement of 99.7%. Coefficient alpha on this sample was .84.

Procedure

We assessed students in the fall of first grade. In September, whole-class screening lasted 15 min; individual screening, 5 min. In September and October, we individually tested children on the remaining measures in three 45- to 60-min sessions. Tests were administered by trained examiners, each of whom had demonstrated 100% accuracy in following standard test procedures during mock administrations. All individual sessions were audiotaped, and 15% of tapes, distributed equally across testers, were selected randomly for accuracy checks by an independent scorer. Agreement was between 99.5% and 99.9%. In October, teachers also completed the SWAN Rating Scale on each student.

Results

A principal components factor analysis across WDRB Listening Comprehension and WASI Vocabulary yielded one factor; thus, we created a weighted composite language variable. Each of the remaining constructs was assessed with one measure: for concept formation, WJ–III Concept Formation; for nonverbal problem solving, WASI Matrix Reasoning; for attentive behavior, SWAN; for working memory, the phonological loop, and the visuospatial sketchpad, summary scores from the WMTB–C subtests; for processing speed, WJ–III Visual Matching. The numerosity measures were Number Line Estimation and the Number Sets Test. The two mathematics outcomes were NCs and WPs. In Table 1, we show raw and standard score means and standard deviations, along with zero-order correlations.

Predictors of Number Combination Skill

We contrasted two models in predicting individual differences in NC skill (see Table 2). In Model 1-NC, we tested the effects of the two numerosity measures, entering Number Line Estimation and the Number Sets Test simultaneously into the regression analysis. Each was a significant predictor in the presence of the other. Overall, Number Line Estimation (negative scores represent accurate placements) and the Number Sets Test (i.e., d' score) explained 65.6% of the variance in NC skill, $F(2, 202) = 192.75$, $p < .001$. Partitioning this variance revealed that 36.9% of the explained variance was shared between Number Line Estimation and the Number Sets Test, 58.5% was unique to Number Sets Test, and 4.6% was unique to Number Line Estimation.

Model 2-NC shows that each numerosity measure (Number Line Estimation and the Number Sets Test) was a significant predictor of NC skill in the presence of the eight domain-general abilities. The only domain-general ability that was a uniquely significant predictor of NC skill was attentive behavior. Overall, the two numerosity measures and the eight domain-general abilities explained 67.7% of the variance in NC skill; the addition of the eight domain-general abilities did not significantly increase R^2: 2.1% increase, F change $(8, 194) = 1.56$, $p = .141$. Partitioning Model 2-NC variance between the numerosity measures and the domain-general abilities revealed that 62.0% of the

explained variance was shared, 34.9% was unique to the numerosity measures, and 3.1% was unique to domain-general abilities.

Predictors of WP Skill

We followed the same procedure in predicting individual differences in WP skill (see Table 3). In Model 1-WP, each numerosity measure (Number Line Estimation and the Number Sets Test) was a significant predictor in the presence of the other. Together, Number Line Estimation and the Number Sets Test explained 44.4% of the variance in WP skill, $F(2, 202) = 80.66$, $p < .001$. Partitioning this variance revealed that 38.7% of the explained variance was shared between Number Line Estimation and the Number Sets Test, 55.2% was unique to d', and 6.1% was unique to Number Line Estimation.

In Model 2-WP, the Number Sets Test but not Number Line Estimation was a significant predictor of WP skill in the presence of the eight domain-general abilities. The domain-general abilities that were uniquely significant predictors of WP skill were the central executive component of working memory and concept formation, with a trend for language ability ($p = .069$). Overall, the numerosity measures and the eight domain-general abilities explained 55.2% of the variance in WP skill, with the addition of the domain-general abilities resulting in a substantial (10.8%) and significant increase in R^2, F change(8, 194) = 5.82, $p < .001$. Partitioning Model 2-WP variance between the numerosity measures and the domain-general abilities revealed that 68.3% of the explained variance was shared, 12.1% was unique to the numerosity measures, and 19.6% was unique to domain-general abilities.

Discussion

We assessed the relative contributions of domain-general abilities and domain-specific numerical competencies on individual differences in first graders' NC and WP skill. We focused first on NC skill because the National Mathematics Advisory Panel (2008) and the National Council of Teachers of Mathematics (2006) identified NC fluency as a core arithmetic skill, and because attaining NC fluency is difficult for many children (e.g., Goldman, Pellegrino, & Mertz, 1988).

We began by comparing the relative contributions of measures representing the two hypothesized number sense systems to the prediction of individual differences in NC skill. We entered a measure of approximate representation of large quantities (i.e., Number Line Estimation; Siegler & Booth, 2004) and a measure of exact representation of small quantities (i.e., d' from the Number Sets Test; Geary et al., 2009) simultaneously into regression analysis predicting NC skill. Each was a significant predictor in the presence of the other, and the two numerosity measures together accounted for a large proportion of the variance (65.6%). This suggests that both core systems hypothesized to comprise number sense contribute to the development of NC skill. Even so, most (58.5% of the 65.6%) of this variance was unique to the measure of exact representations of small quantities (i.e., the Number Sets Test), with 36.9% of the explained variance shared between the two numerosity constructs and only 4.6% attributable specifically to approximate representation of large quantities (i.e., Number Line Estimation).

The importance of the approximate system of number in NC skill development is in keeping with findings of some recent studies (Gilmore et al., 2007; Halberda, Mazzocco, & Feigenson, 2008). Yet, our results suggest that fluency in accessing exact representations of small quantities may be more essential. This makes sense given that NC skill and items on the Number Sets Test require quick recognition and combination of small magnitudes. One possibility is that children who have a strong foundation for verbally subitizing and adding the corresponding quantities are at an advantage in learning NC. This might explain Koontz and Berch's (1996) finding that children with mathematics disability have a smaller subitizing range; it may also explain the common finding that children with mathematics disability have difficulty learning NCs (Geary, 1993). At the same time, it is likely that for other types of mathematics performance, approximate representation of large quantities is the more essential system. In that vein, Booth and Siegler (2008) provided data suggesting the potential importance of Number Line Estimation in predicting students' learning of an addition estimation task. The authors did not, however, consider exact representation of small quantities as a competing predictor. In future studies, researchers might simultaneously consider the two hypothesized core systems of number sense when investigating various aspects of mathematics performance, as done in the present study. In any case, our results support Duncan et al.'s (2008) conclusion about the importance of early numerical competence for supporting formal mathematical learning in school.

After examining the effects of the two numerosity measures on NC skill, we contrasted a model that assessed the effects of the numerosity measures in the presence of the eight domain-general abilities. In this much more stringent test, both numerosity measures retained their status as unique predictors. On this basis, we conclude that each of the two hypothesized core systems of number sense directly affects the development of NC skill even when controlling for the variance associated with a host of domain-general abilities. Just as interesting, however, results showed that the addition of the domain-general abilities resulted in only a small, nonsignificant (2.1%) increase in R^2. This was the case even though several of our measures of domain-general abilities (i.e., central executive, phonological loop, and processing speed) involved numerals. As per Landerl, Bevan, and Butterworth (2004), this creates a stringent test of the domain-specific hypothesis due to the potential for confounding domain-general abilities with numerical processing abilities. In a similar way, because we excluded 73 students due to mathematics performance that was inconsistent with their overall risk status, it is possible that results are biased toward a domain-general perspective, creating an even more stringent test of the domain-specific hypothesis.

Yet, our findings lend support for a domain-specific perspective on NC skill, not only indicating that both hypothesized aspects of numerosity are important in NC skill but also that (a) NC skill does not depend on domain-general abilities above and beyond the influence of numerosity and (b) domain-general abilities do not mediate the effects of numerosity on NC skill. This suggests that NC skill grows out of the development of meaningful and interconnected knowledge about numbers that may have their foundation in children's early ability to subitize and estimate magnitude (e.g., Baroody et al., 2009). In the present study, we did not address whether individual differences in numerosity result from innate differences or from the nature of socially mediated preschool experiences. Regardless of how these individual differences develop, results indicate the importance of providing strong preschool opportunities to help children construct a strong sense of numerosity.

At the same time, however, we also examined how much of the variance in domain-general abilities and numerosity variables is unique versus shared when explaining NC skill. Partitioning the variance revealed that although 34.9% of the explained variance was unique to the numerosity measures (and only 3.1% was unique to domain-general abilities), 62.0% of the explained variance was shared. Finding that a substantial amount of variance is shared indicates the need for additional research on the viability of a combined perspective. Geary et al. (2009) demonstrated that although performance on the Number Sets Test appears to capture fluency in processing basic numerical information, it is influenced by the central executive and general cognitive ability. Whether this represents method variance in the construction of the Number Sets Test or whether working memory and cognitive ability are important for the functional use of domain-specific number representations during mathematics learning remains to be determined.

Our last question centered on whether the relations for NC skill apply to WP performance, which requires but is not limited to NC skill. When Number Line Estimation and the Number Sets Test were simultaneously entered into regression analysis to predict WP performance, each was a significant predictor in the presence of the other, as was the case for NC skill. However, these numerosity variables accounted for less (44.4%) of the explained variance in WP skill compared to NC performance (65.6%). So it was not surprising that when we assessed the effects of the numerosity measures in the presence of the eight domain-general abilities, this more stringent test revealed that only one of these core systems of number sense, exact representation of small quantities (i.e., *d′* of the Number Sets Test), not approximate representation of large quantities (i.e., Number Line Estimation), was a unique predictor. This indicates that only exact representation of small quantities exerts a direct effect on WP skill whereas the effects of approximate representation of large quantities are mediated by the domain-general abilities.

In fact, the addition of the set of domain-general measures resulted in a substantial (10.8%) and significant increase in explained variance in WP skill. This stands in stark contrast to the finding that domain-general abilities together did not improve the prediction of NC performance beyond what was captured by the numerosity measures. Moreover, partitioning the variance between the numerosity measures and the domain-general abilities revealed that more variance was attributable to domain-general abilities (19.6%) than to the numerosity measures (12.1%). By contrast, in predicting NC skill, the corresponding percentages were 3.1 and 34.0. In line with the prediction of NC skill, however, a hefty portion (68.3%) of the explained variance was shared between numerosity and domain-general abilities, again suggesting additional research on the viability of a combined perspective.

In conducting research to understand which domain-general abilities may underlie WP skill, our findings indicate the importance of three abilities. First, the central executive component of working memory was uniquely predictive of WP performance, even when two numerosity and seven other domain-general abilities were competing for variance. Theoretical frameworks posit that WPs involve construction of a problem model that requires working memory (e.g., Kintsch & Greeno, 1985). Much of the literature, including the present results, provides support for this theoretical framework (e.g., Fuchs et al., 2005; Swanson & Beebe-Frankenberger, 2004; Swanson & Sachse-Lee, 2001), although findings are not consistent (e.g., Fuchs et al., 2006; Fuchs, Fuchs, Stuebing, et al., 2008; Vukovic & Siegal, 2010).

A second potentially important domain-general ability in determining WP skill, as reflected in the present study, is concept formation. As with the central executive, concept formation was uniquely predictive of WP performance, even when two numerosity and seven other domain-general abilities were competing for variance. Concept formation involves identifying, categorizing, and determining rules to classify objects and therefore appears to represent general reasoning or problem-solving ability, as is required in WPs. In prior research, concept formation has also emerged as a determinant of WP skill (Fuchs et al., 2006; Fuchs, Fuchs, Stuebing, et al., 2008; Swanson & Sachse-Lee, 2001). Additional studies are needed to determine whether concept formation predicts ease of learning and transferring WP schemas (e.g., Fuchs, Fuchs, Craddock, et al., 2008; Sweller, 2004).

The present results also suggest the potential importance of a third domain-general ability: language. Although it only approached statistical significance ($p = .069$), we nonetheless discuss this finding because prior studies strongly support the role of language in WP performance, thereby suggesting the appropriateness of a one-tailed test of significance. Jordan et al. (1995) documented the importance of language when kindergarten and first-grade language-impaired children performed lower than unimpaired peers on WPs. Fuchs et al. (2006) showed its relation to WP skill among third graders while controlling for a host of other variables, and profile analysis (Fuchs, Fuchs, Stuebing, et al., 2008) demonstrated that poor language ability was the domain-general ability that reliably distinguished third graders with WP deficits from those with specific calculation deficits. Moreover, it makes sense that language supports WP performance given the obvious need to process linguistic information when building representations of WPs.

In a more general way, the pattern of findings in the present study, whereby the role of numerosity and domain-general abilities differed across NC and WP skill, also suggests that not all aspects of mathematics performance tap the same underlying abilities. These findings lend support for the notion that NC and WP skill may represent distinct domains of mathematical cognition. Results echo Fuchs, Fuchs, Stuebing, et al. (2008), in which third-grade students at the lower end of the performance range in calculations versus WPs showed distinctive cognitive profiles, and Hart, Petrill, Thompson, and Plomin (2009), who found that mathematics problem solving has different genetic and environmental influences than mathematics calculation. Together, these studies suggest that the development of mathematical cognition does not depend on a uniform set of numerical or general cognitive competencies but rather that the relative contributions of numerosity and domain-general explanations to the development of mathematical cognition differ depending on the nature of mathematics performance. In fact, elementary-school mathematics is conceptualized in strands (e.g., concepts, numeration, measurement, arithmetic, algorithmic computation, and problem solving), and high school curriculum offerings include algebra, geometry, trigonometry, and calculus. Yet, little is understood about how aspects of mathematical cognition relate to each other: which are shared or distinct or how development in one domain corresponds with development in another or how learning in one domain promotes learning in another. Research is needed to expand theoretical insight into the nature of these types of mathematical competence and their development.

Children's Classroom Engagement and School Readiness Gains in Prekindergarten

Child engagement in prekindergarten classrooms was examined using 2,751 children (mean age = 4.62) enrolled in public prekindergarten programs that were part of the Multi-State Study of Pre-Kindergarten and the State-Wide Early Education Programs Study. Latent class analysis was used to classify children into 4 profiles of classroom engagement: *free play*, *individual instruction*, *group instruction*, and *scaffolded learning*. *Free play* children exhibited smaller gains across the prekindergarten year on indicators of language/literacy and mathematics compared to other children. *Individual instruction* children made greater gains than other children on the Woodcock Johnson Applied Problems. Poor children in the *individual instruction* profile fared better than nonpoor children in that profile; in all other snapshot profiles, poor children fared worse than nonpoor children.

There is growing concern about children's lack of readiness for school (Bowman, Donovan, & Burns, 2000). Evidence suggests that children's school readiness, particularly for children from disadvantaged backgrounds, is enhanced in prekindergarten programs during the year before kindergarten (e.g., Magnuson, Meyers, Ruhm, & Waldfogel, 2004). About three fourths of the states now offer such programs (Barnett, Hustedt, Friedman, Boyd, & Ainsworth, 2007). Identification of program characteristics related to improving skills is important given the huge investment of tax dollars and the importance of having vulnerable children enter school ready to learn. The current study describes patterns of children's engagement in prekindergarten classrooms. Specifically, we used person-centered analyses to group children into profiles (i.e., groups) of classroom engagement that reflected the dominant literatures on early childhood education. Then, we explored whether profile membership was linked to gains in school readiness during the prekindergarten year. Additionally, we examined whether some profiles were particularly beneficial for poor children.

Classroom Quality: Children's Classroom Engagement Instead of Classroom Environment

Higher quality prekindergarten programs are associated with more positive child outcomes (e.g., Burchinal et al., 2000). The literature on child-care environmental quality is primarily based on both constructivist theory, in which the adults' role is to provide children with rich materials that promote child-initiated exploration (Ginsburg & Opper, 1988), and sociocultural theory, in which the adults'

The NCEDL Multi-State and SWEEP Study of Pre-Kindergarten were conducted by a team of researchers, including Oscar A. Barbarin, Donna M. Bryant, Margaret Burchinal, Richard M. Clifford, Diane M. Early, Carollee Howes, and Robert C. Pianta. This study is supported under the Educational Research and Development Center Program, PR/Award R307A60004, as administered by the Institute of Education Sciences, U.S. Department of Education. However, the contents do not necessarily represent the positions or policies of the U.S. Department of Education, and endorsement by the federal government should not be assumed. NCEDL is grateful for the help of the many children, parents, teachers, administrators, and field staff who part of this study.

role is to provide frequent sensitive and responsive interactions with children (Vygotsky, 1962). The assessment of quality is typically at the classroom level and involves global assessments across all activities. Many measures focus on the teacher, although some widely used measures examine the relationship between an individual child and teacher.

Examining children's classroom engagement can provide additional information that is not available in the environmental quality assessments. The importance of focusing on child-level experiences is stressed in Howes's theoretical model for children's child-care experiences (Howes, 2000), where children's experiences—play activities, peer play, and relationships—are embedded within the context of the classroom. That is, although measures of child-care environmental quality describe the context within which child engagement occurs, a direct examination of child engagement at the child level is needed to understand exactly what children are doing—what activities are occupying children's time—within those contexts. Although children's engagement and the classroom social context certainly influence each other (e.g., Howes & Smith, 1995), they remain distinct constructs.

Another reason to look beyond environmental quality to classroom engagement is that common measures of classroom environmental quality might not adequately capture dimensions of the classroom that are linked to child outcomes. A meta-analysis of 20 studies of the relation between measures of child-care quality and child outcomes showed that the relation is weak (r = .12; Burchinal et al., 2008). The types of activities and level of interactions with the caregiver are also known to be important in predicting preschool children's learning in child-care settings (Howes et al., 2008).

A Person-Centered Approach

Child engagement has thus far been examined using regression, which examines each child engagement activity individually (e.g., Howes et al., 2008). Another method is a person-centered approach, which would consider the entire spectrum of activity engagement of each child to place children into profiles, or subgroups. As such, children within the same profile would exhibit more similar patterns of classroom engagement than children in different profiles. A person-centered approach is more holistic than regression because it considers the entire constellation of child engagement rather than one child engagement at a time.

One type of person-centered analysis, cluster analysis, was used in an earlier study that clustered children based on their classroom engagement (Tonyan & Howes, 2003). Latent class analysis (LCA) is another person-centered approach that offers several advantages over cluster analysis. One advantage is that LCA provides model fit statistics that allow assessment of the model fit to the data, and the appropriateness of the number of profiles specified. In addition, because LCA is model based, the same results can theoretically be replicated with an independent sample (Muthén & Muthén, 2000). LCA would be an ideal method for identifying profiles of children based on their patterns of classroom engagement.

Patterns of Classroom Engagement

Based on dominant models of early childhood education (e.g., the constructivist or sociocultural models), three profiles might be expected to emerge from a LCA of children's classroom engagement: a profile that emphasizes free-choice play and exploration, a profile that emphasizes teacher instruction, and a profile that emphasizes teacher scaffolding.

One model of early childhood education encourages child-directed exploration in activities that the child chooses, positing that many developmental competencies are acquired only through play (Johnson, Christie, Yawkey, & Wardle, 1987). For example, sociodramatic play develops language and problem-solving skills; constructive play (e.g., blocks) helps children learn about symmetry and practice making mental plans. These skills, according to this model, are not readily learned via teacher instruction. Based on this model, we expect to see a profile of children that engages in primarily free-choice play activities.

A second model of early childhood education posits that children learn most from teacher instructional support, defined as large amounts of literacy instruction, high-quality teacher feedback, and teacher-led discussions that elicit cognitive skills (Hamre & Pianta, 2005). One study reported that more class time spent on direct and explicit instruction involving teacher feedback was linked to higher levels of student achievement (Meyer, Wardrop, Hastings, & Linn, 1993; Pianta, La Paro, Payne, Cox, & Bradley, 2002). Another study found that increased instructional time in each of four preacademic activities—letter-sound, oral language, being read to, and mathematics—was associated with higher teacher ratings of children's language and literacy skills (Howes et al., 2008). Based on this model, we expect to see a profile of children that spends a lot of time in teacher-directed instructional activities.

A third model of learning emphasizes the importance of "scaffolding" by a more knowledgeable other that enables children to think and complete tasks at a higher level than if they were unassisted (Wood, Bruner, & Ross, 1976). An important element of quality early childhood education is teacher scaffolding of children's learning (Smith, 1996), including scaffolding to develop young children's literacy (Henderson, Many, Wellborn, & Ward, 2002). Because whether scaffolding occurs during free play or teacher instruction is less important, we might expect a third profile of children who are not distinguishable from other children by their engagement in free play or instructional time, but rather in their receipt of teacher scaffolding.

Different models of classroom engagement may be more beneficial for different types of child outcomes. Children in classrooms that give children opportunities for free play and exploration might have more developed language and advanced mathematics and spatial skills (Johnson et al., 1987), according to the literature on free-choice play. Children in classrooms utilizing the instructional model might be expected to make greater gains in basic academic skills such as knowing numbers and letters and how to write their names, because these are skills more readily taught via teacher instruction and less likely learned through free play. Children in classrooms utilizing scaffolding might have more developed literacy skills (Henderson et al., 2002) or problem-solving skills (Rogoff, 1990). Including a variety of child outcomes makes it possible to assess whether certain models of early childhood education are best suited for particular domains of learning.

Child Engagement and Poverty Status

Children's classroom engagement may also be linked to their poverty status. One study found, via teacher interviews, notable differences in the reported beliefs of preschool teachers of lower versus middle socioeconomic status (SES) children (Lee & Ginsburg, 2007). Teachers of lower SES children reported explicitly focusing on developing children's literacy and mathematics skills through direct instruction to prepare children for kindergarten. Teachers of higher SES children, on the other hand, reported developing skills more indirectly by allowing children to engage in the literacy or mathematics activities of their choice in a classroom environment filled with rich learning materials. We therefore expect children's classroom engagement to differ by poverty status, consistent with teacher beliefs reported in this study.

If preschool teachers of low- versus middle-income children have different beliefs about what constitutes an ideal preschool education, is there any evidence that their beliefs are accurate? That is, do low-income children indeed benefit more from a focus on mathematics and literacy skill development, whereas middle-income children benefit more from the freedom to choose activities? One study found that children who were at risk of school failure benefited more from classrooms with more direct literacy instruction, evaluative feedback, and instructional conversations during teacher-led discussions, compared to children who were not at risk (Hamre & Pianta, 2005). Therefore, poor children might be expected to benefit more from direct instruction of academic skills than from child-initiated free-play activities.

In the current study, we used LCA to classify children into profiles based on their classroom engagement. We then used profile membership to predict children's gains from fall to spring of the prekindergarten year, in the areas of language and literacy and mathematics. Next, we examined sociodemographic differences across the class engagement profiles. Finally, we assessed whether different child engagement profiles provided different amounts of gains for poor versus nonpoor children.

Method

Participants

Study data come from the National Center for Early Development and Learning Multi-State Study of Pre-Kindergarten, and a follow-up study, the State-Wide Early Education Programs Study (SWEEP). Both studies used a stratified random sampling method to select programs within states, classrooms within programs, and children within classrooms. States with large numbers of children enrolled in public prekindergarten and with programs that have had time to mature were selected. The Multi-State included six states (California, Illinois, Georgia, Kentucky, New York, and Ohio), with 40 programs selected from each state, and began in fall of 2001; the SWEEP included five states (Massachusetts, New Jersey, Texas, Washington, and Wisconsin), with 100 programs selected from each state, and began in fall of 2003. Programs were diverse with regard to urbanicity. All programs were state funded, although funding streams differed within and across states; 15% of programs were part of Head Start programs. A total of 701 programs participated, and one classroom was randomly selected from each program. In both the Multi-State and the SWEEP, 94% of classroom teachers agreed to participate. In the Multi-State and SWEEP, 61% and 55% of parents, respectively, gave consent to participate. Of the children with parent consent, four children (two boys and two girls) from each classroom were randomly selected to participate, making for a total of 2,966 children.

Sample classrooms had an average class size of 19 children and an adult–child ratio of 1:8.6. A majority of the children (58%) were from families living below the federal poverty line, and about half were boys (49%). The sample included children who were European American (41%), African American (18%), Latino (27%), Asian American (4%), Native American (1%), and of other ethnicities (10%). Mean maternal education was 12.8 years. Children with no classroom engagement observations ($n = 215$) were dropped from the study, resulting in a final sample of 2,751 children.

Measures

Classroom Observations

The Emerging Academics Snapshot (Ritchie, Howes, Kraft-Sayre, & Weister, 2001) is a measure of children's classroom engagement that captures children's moment-to-moment activities. Observations were conducted over 2 days in the Multi-State and over 1 day in the SWEEP, each in the spring. Each child was observed in 20-s interval "snapshots," followed by a 40-s coding period. The data collector then observed each of the other study children in that classroom before coming back to observe the first child again, continuing in this manner for the entire day. During each 20-s snapshot, children were coded with one of six mutually exclusive *activity settings*: basics, free choice, individual time, meals, small group, and whole group; one or more *preacademic engagements*: esthetics, fine motor skills, gross motor skills, letter and sound, mathematics, oral language development, prereading, read to, science, social studies, and writing; and one or more *teacher–child interactions*: routine, minimal, simple, elaborated, scaffolding, and didactic (see Table 1 for a detailed description of each child engagement). Kappas range from .70 to .87.

Global classroom environmental quality was assessed using the Early Childhood Education Rating System–Revised (ECERS–R; Harms, Clifford, & Cryer, 1998) and the Classroom Assessment Scoring System (CLASS; Pianta, La Paro, & Hamre, 2004). The ECERS–R assesses aspects of the preschool classroom, such as room arrangement and furnishings and relaxation. Scores from the Multi-State study reflect the mean of a fall and a spring observation, and scores from the SWEEP study reflect a single observation day in the fall. Composite ECERS–R scores range from 1 (*inadequate quality*) to 7 (*excellent quality*). Factor analysis of the ECERS–R yielded two factors, one of which was used in the current study: the Teaching and Interactions factor, which consisted of items such as Encouraging Children to Communicate, Discipline, and Interactions among Children. The CLASS rates the emotional climate, classroom climate, and instructional supports for learning in early childhood classrooms. Classrooms were rated from 1 (*low*) to 7 (*high*) on nine dimensions, such as Positive Climate, Teacher Sensitivity, and Concept Development. Data collectors rated the classroom and teacher on the nine dimensions about every 30 min throughout an observation day. The CLASS scores for children in the Multi-State study reflect the mean of a fall and a spring observation, and for children in the SWEEP study a single observation day in the spring. Factor analysis of the CLASS yielded two factors, one of which was used in the current study: Instructional Climate, which is a composite of Concept Development and Quality of Feedback.

Centralized training of all observers was conducted for the three classroom observations. Prior to data collection, observers were certified via reliability tests that compared observers' ratings with experts' ratings. Interrater agreement was evaluated using weighted Kappas, which adjust for agreement due to chance; observers with an overall kappa of at least .60 were certified (see Pianta et al., 2005, for complete details). Kappas ranged from .65 to .81. for the ECERS–R, CLASS, and Snapshot; Kappas of .65 or higher indicate good agreement (Landis & Koch, 1977).

Indicators of School Readiness

Direct child assessments. In the fall and spring, children's language, preliteracy, and mathematics skills were conducted by a different data collector

Table 1
Definitions for the Emerging Academics Snapshot

Code	Description
Activity settings	
Basics	Napping, toileting, standing in line, cleaning up, or waiting between activities
Free choice	Child selects what and where to play or learn, engaging in activities such as individual art projects, blocks, pretend play, and reading
Individual time	Child and the rest of the class each work on a project independently, such as a worksheet or on the computer. The teacher moves around to help
Meals	Eating lunch, breakfast, or snacks
Small group	Small-group activities that are teacher organized or teacher led, such as group art projects, writing stories, or collective building
Whole group	Whole-group activities that are teacher initiated, such as stories, songs, calendar, discussions, book reading, and demonstrations
Preacademic and academic activities	
Esthetics	Art, drama, or music activities
Fine motor	Stringing beads, building with Legos, cutting, or using crayons and markers
Gross motor	Running, skipping, jumping, swinging, riding bikes, or playing games such as basketball, catch, run and chase, dancing, or musical chairs
Letter and sound	With guidance from teacher, child identifies letters, sounds out words, talks about letter-sound relationships, recognizes sounds using rhymes
Mathematics	Rote counting, counting with one-to-one correspondence, skip counting, matching numbers to pictures, making graphs, or playing counting games
Oral language	Child interacts with teacher or peers in talking about stories, or telling development stories of their own, or answering and asking open-ended questions
Prereading	Reading stories, identifying words, recognizing symbols and pictures as having meaning, or practicing a class poem
Read to	Teacher reads books and stories to child, engages in talking about the author, showing the cover, or asking questions about the book
Science	Child explores natural phenomena in their environment, uses science equipment, and reads books or talks about animals, body parts, and life cycles
Social studies	Talking, reading, or engaging in activities about their world (e.g., their neighborhood, their school, the farm, the community workers)
Writing	Writing (or using a computer keyboard to write) numbers or letters
Teacher–child interactions	
Routine	Teacher engages in routine caregiving (e.g., wipe child's nose)
Minimal	Teacher answers child's direct requests for help, or gives simple verbal directives with no reply encouraged, such as "okay," "stop that!"
Simple	Teacher uses some warm or helpful physical contact or verbally answers the child's verbal bids but does not elaborate
Elaborated	Teacher engages in some physical response (e.g., thumbs up, high fives, frown, glare) or acknowledges the child's statements and responds
Scaffold	Teacher (or a more capable peer) does one-on-one work with child and builds on child's initiations, using visuals, concrete objects, and gestures to help child learn. Teacher elicits responses and helps child expand his or her thoughts
Didactic	Teacher lectures, gives instructions, models, asks close-ended questions, or demonstrates, such as counting or saying the days of the week

from the one who conducted the classroom observations.

Children who spoke a home language other than English were given an English language screener, the Pre-LAS2000 (Duncan & De Avila, 1998). The Pre-LAS was first administered in the fall, and children who did not pass in the fall were assessed again in the spring (fall: $\alpha = .89$; spring: $\alpha = .89$). Children who passed the screener (a score of 31 or higher of 40) were administered the English assessment battery (fall: $n = 147$; spring: $n = 117$). Children who did not pass the screener and who spoke Spanish at home were administered the Spanish assessment battery (fall:

$n = 394$; spring: $n = 317$). Children who did not pass the screener and who spoke a language other than Spanish at home were not assessed in the Multi-State but were assessed in English in the SWEEP (fall: $n = 39$; spring: $n = 11$). With the exception of the Peabody Picture Vocabulary Test (PPVT) and the Test de Vocabulario en Imagenes Peabody (TVIP), English and Spanish assessments were collapsed for analysis so that children who were administered the fall assessments in Spanish and the spring assessments in English (i.e., the 117 children who passed the Pre-LAS in the spring) could be retained for analysis.

The PPVT–3rd Edition (PPVT–III; Dunn & Dunn, 1997) is a test of English receptive vocabulary where the child was shown a set of four pictures at a time and asked to select the picture that best represents the word spoken by the examiner (fall: $\alpha = .96$; spring: $\alpha = .96$). A standardized score was computed for this scale. The TVIP (Dunn, Lugo, Padilla, & Dunn, 1986) is the Spanish version of the PPVT (fall: $\alpha = .92$; spring: $\alpha = .93$).

The Oral and Written Language Scale–Oral Expression Scale (OWLS; Carrow-Woolfolk, 1995) assesses children's understanding and use of spoken language (English only; fall: $\alpha = .92$; spring: $\alpha = .91$). After receiving the examiner's verbal stimulus, the child looked at a picture board and responded orally by answering a question, completing a sentence, or generating a sentence. A standardized score was computed for this scale.

Woodcock-Johnson (WJ) III Tests of Achievement (Woodcock, McGrew, & Mather, 2001) are well-established measures of academic achievement, and the Spanish versions are the Batería Woodcock-Muñoz-Revisada: Pruebas de Aprovechamiento (Woodcock & Munoz-Sandoval, 1996). The Applied Problems subtest is a mathematics test that assessed children's ability to comprehend the nature of a problem, identify relevant information, and perform simple calculations (English fall: $\alpha = .84$; English spring: $\alpha = .83$; Spanish fall: $\alpha = .81$; Spanish spring: $\alpha = .79$). The Letter–Word Identification subtest, administered in the SWEEP study only ($n = 1805$), asks children to identify letters and then words (English fall: $\alpha = .89$ English spring: $\alpha = .83$; Spanish fall: $\alpha = .65$; Spanish spring: $\alpha = .89$). Most children moved beyond identifying letters to identifying words—that is, their ceiling set included word identification.

Children's ability to identify letters, numbers, and colors, to count, and to write their names were assessed in both the English and Spanish assessment batteries. For identifying letters, children were shown a set of mixed capital and lowercase letters and asked to identify as many as they could; the maximum score was 26. For identifying numbers, children were shown a sheet of numbers from 1 to 10, presented in random order, and asked to identify as many as they could; the maximum score was 10. For naming colors, children were presented with a page of 10 different colored bears and asked to name the colors; the maximum score was 10. Alphas for identifying letters, numbers and colors for the English and Spanish assessments ranged from .81 to .97. For the counting task, children were asked to count and point with one-to-one correspondence using a picture card with 20 teddy bears. If the child counted to 20 correctly, another sheet of 20 teddy bears was presented to allow continued counting. Finally, children wrote their names and the percent of their name written legibly was calculated.

Teacher report. Teacher report of children's language and literacy skills in the fall and spring was an average of nine items from the teacher questionnaire of the Early Childhood Longitudinal Studies–Kindergarten Cohort (West, Denton, & Germino-Hausken, 2000). The items assessed children's proficiency in speaking (e.g., using complex sentence structure), listening, early reading (e.g., predicting what will happen next), and early writing (e.g., using initial consonants to spell words). The items were rated on a scale from 1 (*not yet*) to 5 (*proficient*; fall: $\alpha = .91$; spring: $\alpha = .92$).

Poverty Status

Information was obtained on whether the children's family lived below the federal poverty threshold ($17,960 for a family of four in 2001; $18,660 for the same family in 2003).

Sociodemographic Covariates

The analysis of group differences across school readiness used the following covariates: child gender, child ethnicity, household size, poverty status, mothers' years of education, and child age at the spring assessment.

Results

Descriptives

The proportion of a day a child spent in a particular activity or setting was computed as the ratio of the number of intervals the activity or setting was observed divided by the total number of intervals the child was observed. Mean proportions of a day children spent in each activity setting, teacher–child interaction, and preacademic activity are summarized in Table 2.

In terms of activity settings, children spent the largest amount of time in free-choice (30%) and whole-group activities (27%), and the least amount of time in individual time (7%) and meals (7%). In terms of preacademic activities, children spent the most time on esthetics (15%), social studies (15%), and science (11%); the least amount of time was spent in prereading (3%), letter–sound (4%), and being read to (5%). In terms of teacher–child interactions, children spent the largest amount of time in didactic interactions (31%) and the second largest amount of time in scaffolding (9%); the least amount of time was spent in routine interactions (1%).

Some of the school readiness indicators were correlated. In language and literacy, the following pairs of outcomes had a correlation coefficient of .45 or higher: naming letters and WJ Letter–Word ($r = .66$; all results reported as significant are $p < .05$ or better), naming letters and percent name written legibly ($r = .45$), naming letters and teacher report of language and literacy ($r = .49$), and OWLS and PPVT ($r = .68$). In mathematics, the following indicator pairs had a correlation coefficient of .45 or higher: WJ applied problems and naming numbers ($r = .55$), WJ applied problems and highest number counted ($r = .49$), and naming numbers and highest number counted ($r = .55$).

[a]Bonferroni post hoc contrasts were used.

Latent Class Analysis

Latent class analysis was conducted in a series of steps, the first of which was fitting a one-profile model to the data to establish a baseline. Models with successively increasing numbers of profiles (up to a model with five profiles, which failed to converge) were then tested. Models were compared using the following model fit indices: the Akaike information criterion (AIC; Akaike, 1987), the Bayesian information criterion (BIC; Schwartz, 1978), and the adjusted BIC (ABIC; Sclove, 1987). Smaller values on these indices indicate better fit, but there is no criterion for "good" fit; therefore, these values are only useful for comparing two or more models. Additionally, an entropy approaching 1.0 indicates a clear distinction between profiles (Celeux & Soromenho, 1996). The four-profile model was the best fitting model with the smallest AIC (−186005.275), BIC (−185277.150), and ABIC (−185667.961), and the largest entropy (0.825). The LCA models were tested using Mplus (Version 4.0; Muthén & Muthén, 1998-2006).

Profiles 1, 2, 3, and 4 included 51%, 9%, 27%, and 13% of the children, respectively. Means and standard deviations of classroom engagements for each profile are summarized in Table 2. Using analysis of variance (ANOVA), we identified significant differences in classroom engagement across profiles. Children in Profile 1 spent by far the most time in free choice (41%), compared to other profiles, and less time than all other groups on a variety of preacademic engagements. Profile 1 is therefore labeled the "free play" profile. Children in Profile 1 also spent a little more time engaged in gross motor activities (8%) than any other profile and more time than Profiles 2 and 3 in social studies (17%). Children in Profile 2 spent much more time than any other profile in individual time (21%), fine motor skills (17%), and letter–sound (8%). Thus, Profile 2 is labeled the "individual instruction" profile. Children in Profile 3 spent more time than any other profile in whole group (36%) and small group (11%), and this profile is therefore labeled the "group instruction" profile. Children in Profile 4 spent much more time engaged in scaffolding interactions with teachers (21%) than any other profile, and also the most time in elaborated teacher–child interactions (6%). In addition, Profile 4 spent more time than any other profile on many preacademic activities. Therefore, Profile 4 is labeled the "scaffolded learning" profile. Profile 4 spent more time than Profiles 2 and 3 on free-choice activities (29%).

Using ANOVA, we found that the snapshot profiles differed significantly on some demographic characteristics. An examination of household size, maternal education, poverty status, and ethnicity showed that children in the free play and scaffolded learning profiles appeared to be somewhat more privileged than children in the individual instruction and group instruction profiles (see Table 3). Specifically, the free play and scaffolded learning profiles have smaller households and more years of maternal education than children in the individual and group instruction profiles. Children in the indi-

Note. FP = free play profile; II = individual instruction profile; GI = group instruction profile; SL = scaffolded learning profile. Percentages are base rates within each profile.
[a]Bonferroni post hoc contrasts were used.

vidual and group instruction profiles were more likely to be Latino or African American than children in the free play or scaffolded learning profiles. Children in the individual instruction profile were also most likely to be poor compared to all other children. No gender differences emerged between profiles.

Predicting Academic Gains Based on Profile Membership

We assessed the predictive validity of the snapshot profiles by examining fall-to-spring gains in school readiness between the four profiles. We used analysis of covariance (ANCOVA) and covaried for household size, poverty status, maternal education, child race/ethnicity, child gender, and child age. Change was assessed by including fall scores as covariates (i.e., predictors) of the spring scores, such that the residual variance represents change from fall to spring.

Table 4 shows the scores for each profile of children and for each outcome. For example, the score of 12.19 on naming letters in the column "Free play profile" indicates that after adjusting for covariates, children in the free play profile were able to name an average of 12 letters. The overall F tests revealed significant differences across profiles for the following indicators of school readiness: naming letters, WJ letter–word identification, percent of name written legibly, teacher report of language and literacy skills, WJ applied problems, naming numbers, and highest number counted. Bonferroni post hoc contrasts were then used to examine pairwise differences between profiles.

The free play profile made the smallest gains across language and literacy and mathematics.

Table 4
Residual Change Scores From Fall to Spring of Prekindergarten, by Snapshot Profiles

***$p < .001$.

Specifically, the free play profile showed less growth than all other profiles in naming letters, WJ letter–word identification, teacher report of language and literacy skills, and number counting. The free play profile also showed less growth than the individual and group instruction profiles in writing their names, and less growth than the group instruction profile and the scaffolded learning profile on number counting. Finally, the free play profile showed less growth than the individual instruction profile on the WJ applied problems. There was only one significant difference among the individual instruction, group instruction, and scaffolded learning profiles: the individual instruction profile made the greatest gains on the WJ applied problems.

Although effect sizes (partial eta^2) were small, the differences in gains between groups are meaningful. For example, children in the free play profile scored 8 points lower on the WJ letter–word identification than children in the individual and group instruction profiles; this is large for differences that emerged over the course of less than 1 year. Additionally, measurement error for assessments involving younger children tend to be larger than that for older children, and larger measurement errors result in smaller effect sizes (Burchinal, 2008).

In summary, the free play profile showed less growth across indicators of language/literacy and mathematics compared to the other three profiles. The individual instruction profile outperformed all other groups on WJ applied problems.

Snapshot Profiles as Distinct from Classroom Environmental Quality

We wanted to show that the snapshot profiles contribute information about children's classroom experiences that is distinct from and adds to information conveyed by classroom ECERS-R scores. Ideally, we wanted to find no mean differences in ECERS-R scores across the four snapshot profiles. However, there were indeed significant differences: The free play profile ($M = 4.09$, $SD = 0.73$) and the scaffolded learning profile ($M = 4.14$, $SD = 0.75$) each had significantly higher scores than the group instruction profile ($M = 3.42$, $SD = 0.74$) and the individual instruction profile ($M = 3.17$, $SD = 0.63$). In spite of finding significant mean differences, the fairly large standard deviations of ECERS–R scores indicates significant overlap in ECERS–R scores across different snapshot profiles; this in turn suggests that the snapshot profiles provide information not already conveyed by the ECERS–R scores.

To further examine whether the Snapshot profiles contain unique information about children's experiences, we repeated the ANCOVA by profile membership, adding the ECERS–R Teaching and Interactions Scale and the CLASS Instructional Climate Scale as covariates in two separate sets of analyses. All analyses yielded nearly identical results to the original analyses, suggesting again that the snapshot profiles captures information about children's experiences unique from that captured by the ECERS–R and CLASS (results are available upon request).

Poverty Status and Children's Classroom Engagement

To test whether the relationship between gains in school readiness and profile membership varied across poverty status, we conducted a 2 (poverty status) × 4 (snapshot profile) ANCOVA, covarying for gender, ethnicity, household size, poverty status, maternal education, and child age. Table 5 shows adjusted mean scores by profile membership and by poverty status; interaction effects are also shown.

The interaction between poverty status and snapshot profile membership was significant for WJ letter–word identification and highest number counted, and there was a marginal effect ($p = .055$) for WJ applied problems.

For WJ letter–word identification, highest number counted, and WJ applied problems, poor children in the free play, group instruction, and scaffolded learning profiles made smaller gains than their nonpoor peers. In the individual instruction profile, however, poor children actually made greater gains than nonpoor children across these measures of school readiness.

Discussion

It is useful to think about classroom engagement in terms of number of minutes children spend on each activity during a typical program day. For example, the most frequent activity setting was free play (30%), which occupied an average of 45 min of a part-day, 2.5 hr program—quite a longtime. In contrast, < 8 min/day was devoted to each of the following literacy activities: prereading (3%), letter–sound (4%), and being read to (5%).

Moving beyond whole-sample averages, there was substantial variation in children's classroom engagement. Using a person-centered approach, we identified four profiles of children with distinct

patterns of classroom engagement: a free play profile for whom class time was dominated by free-choice activities; two instructional profiles that spent a lot of time receiving teacher instruction, whether in an individual or group format; and one scaffolded learning profile that engaged in large amounts of teacher scaffolding.

We had expected a profile of children that received frequent teacher instruction. We did not expect, however, two instructional profiles that were distinct in terms of the format—individual or group—in which they received teacher instruction. Advantages of individual settings include increased attention for teacher directions and greater need for self-regulation while giving children an opportunity to practice skills they already learned (Stright & Supplee, 2002). An advantage of the group activity setting is that children have the opportunity to share ideas and learn from one another. These results suggest that among the teachers who practice the instructional model of early childhood education, some teachers prefer to deliver instruction via individual seatwork while other teachers prefer to deliver instruction via group work.

Next, we found that the free play profile made the smallest fall-to-spring gains across many measures of language and literacy and mathematics compared to the two instructional profiles and the scaffolded learning profile. Recall that we had included a variety of assessments to explore whether different models of early childhood education were best suited for different domains of learning; our results did not support this hypothesis.

Given that the free play profile was by far the largest profile, making up 51% of the sample children, it was discouraging to find that it was also the profile with the smallest gains in child outcomes. Although these results suggest that the instructional and scaffolding models of early childhood education are more beneficial than the free-choice play model, a caveat exists. Recall that the study sample was at higher demographic risk than the national average: A full 58% of the sample is poor, and the average maternal education is only 12.9 years. Recall also the research showing that instructional support was beneficial for at-risk children, but not necessarily for children not at risk (Hamre & Pianta, 2005). It is possible, therefore, that our finding that classroom instruction was more beneficial than free-choice play is partially the result of having a sample of predominantly at-risk children.

Our study results revealed two further points of interest regarding the scaffolded learning profile. First, the scaffolded learning profile spent a large amount of time in free-choice activities (29%): less than the free play profile (41%) but a lot more than either of the instructional profiles (13% and 15%). These results suggest that free play, when accompanied by high-quality scaffolding interactions with teachers, remains a model of classroom engagement that may be conducive to children's learning. Second, it was disappointing that although the scaffolded learning profile had more than twice as many scaffolding interactions with teachers as any other profile, children in this profile did not experience the greatest growth compared to other profiles. Subsequent analysis revealed a possible explanation: Children in the scaffolded learning profile had the highest fall scores across several child outcomes (see Table 6). Recall also that the scaffolded learning profile was the most sociodemographically advantaged of the four profiles with smaller household sizes, a lower likelihood of being poor, and mothers with higher levels of education. As such, these children may have been better prepared for prekindergarten as a result of educational experiences they received in the home. Also, coming from more advantaged families may be directly related to the frequency of scaffolding interactions: These children may experience more scaffolding interactions with parents and therefore may be

more likely to elicit and sustain scaffolding interactions with teachers.

Note that for the individual instruction profile, the standard errors of many child outcome measures are larger than for other profiles; this is because the individual instruction profile had fewer children than the other three profiles. Had the standard errors been smaller, more differences between the individual instruction profile and the free play profile may have been statistically significant. Therefore, the small size of the individual instruction profile had the effect of making the results more conservative.

The study examined a variety of child outcomes—from higher order language and problem-solving skills to basic letter and number recognition skills—that are important predictors of later elementary school reading and mathematics. The WJ battery of achievement tests are good predictors of later academic achievement (McGrew, 1986). Less obvious, perhaps, is that basic skills such as naming letters and counting are also important for later academic success. Basic literacy skills developed in preschool such as naming letters and writing one's own name partially determine reading development in early elementary school (Lonigan, Burgess, & Anthony, 2000; Storch & Whitehurst, 2002). Likewise, the lack of basic mathematics skills in kindergarten, such as the ability to name numbers, predicted having a mathematics learning disability in third grade (Mazzocco & Thompson, 2005). Further evidence from an early mathematics intervention program suggests that teaching basic number sense to children at risk for having difficulties in mathematics improves later mathematics performance (Griffin, Case, & Siegler, 1994). Although middle-class children may have the opportunity to develop these basic skills at home, low-income children may not; therefore, it is all the more important that low-income children learn these skills at school. Indeed, Delpit (1996) made the case that low-income African American children need to be taught basic skills so that they can translate their oral language fluency and creativity—which they already possess—into a format that is recognized by mainstream society.

The snapshot profiles captured information about children's classroom experiences not captured by the ECERS–R or the CLASS. ANCOVA of children's gains across profiles remained unchanged after the ECERS–R Teaching and Interactions Scale and the CLASS Instructional Climate Scale were separately added as covariates. In addition, the two snapshot profiles that exhibited greater gains across the prekindergarten year—the individual and group instruction profiles—actually had lower average composite ECERS–R scores compared to the other two profiles. That is, children in *lower* quality classroom environments (measured by ECERS–R) experienced classroom engagement (measured by the Snapshot) that was associated with *greater* gains in school readiness. These results suggest that the Snapshot captured aspects of children's classroom experiences not captured by the ECERS–R and CLASS.

Looking across poverty status, we found that children in the individual instruction profile were more likely to be poor than children in any other profile. This is consistent with prior research suggesting that teachers of low-SES children tend to focus on developing skills in mathematics and literacy (Lee & Ginsburg, 2007), which are often practiced in individual instruction settings. That the individual instruction profile had the highest proportion of poor children is fortuitously joined by the finding that poor children in the individual instruction profile were the only ones to make greater gains than their nonpoor peers on indicators of mathematics and literacy. This finding is consistent with the view some scholars have expressed that minority and low-income children stand to gain more from a curriculum focused on developing academic skills (Delpit, 1996).

Limitations

Free-choice activities teach children complex skills, such as problem-solving, making plans, and comprehension (Johnson & Yawkey, 1988). Unfortunately, these types of higher order skills were not fully assessed by the measures included in the Multi-State and SWEEP studies; thus, gains made by children in the free play profile may not have been captured. Nonetheless, assessments, such as the PPVT, OWLS, and WJ do capture more advanced language and cognitive abilities, and the free play profile still made smaller gains on these assessments than other children. Although this study may not have included the most ideal measures for capturing gains made by the free play profile, the results nonetheless suggest that children in the free play profile made smaller gains in many important domains of development.

In all analyses, we treated children's English and Spanish scores on various assessments as equivalent (with the exception of the PPVT and TVIP). Although most children were assessed at both time points in the same language, some children

($n = 117$) were administered the Spanish assessments in the fall and, after passing the Pre-LAS in the spring, were administered the English assessments in the spring. Those children would have been dropped had we not combined the English and Spanish scores. Although it is not ideal to calculate child gains with Spanish assessments at the first time point and English at the second, it is a conservative measure of gains that preserves the number of cases without sacrificing the validity of the results.

Peer interactions were not captured by the snapshot measure. However, children certainly learn through peer interactions, including through peer scaffolding interactions with same-ability classmates (King, Staffieri, & Adelgais, 1998). Also, given that a large amount of time was spent in free play, it would have been instructive to capture whether, during free play, children were engaged in peer interaction and, if so, what type of peer interaction (e.g., parallel play, pretend play). Coding an activity setting simply as free play is somewhat limited because very different types of peer interactions, with different outcomes for children's learning, could all occur during free play. Capturing children's peer engagement would have added a rich dimension to further understanding the relationship between classroom engagement and child outcomes.

Several measures of language and literacy and mathematics were moderately or highly correlated. But because many assessments highlight the different strengths of different snapshot profiles, it is still important to include each measure. For example, although WJ applied problems and naming numbers were highly correlated ($r = .55$), the individual instruction profile excelled (compared to other groups) on WJ applied problems only. Furthermore, previous studies have often examined these outcome measures together (Howes et al., 2008).

Implications for Policy and Practice

This study described patterns of children's engagement in prekindergarten classrooms and explores whether some patterns of engagement bring about greater gains for children than others. The environmental quality literature thus far has encouraged preschool teachers to think about the arrangement of physical space and the materials available within classrooms. Results from the current study might encourage teachers to think about the allocation of children's time to various classroom engagements in a way that benefits children's learning.

Increasingly, policy makers and advocacy organizations (e.g., Trust for Early Education, National Institute for Early Education Research) are calling for ''high-quality'' prekindergarten for every child. These findings remind us that quality can be assessed in multiple ways that yield different quality ratings for the same classrooms. For example, a class might receive a relatively high ECERS–R score for ample materials but have low levels of teacher–child interactions and may therefore not be optimally preparing children for school.

Teachers, educators, and policy makers also need to consider the factors contributing to the lack of high-quality teacher–child interactions. As pressures from federal and state mandates increase, and school districts increase demands for school-ready children, teachers are asked to do increasingly more. They are often trying to fit into a very short morning (a) circle time that includes calendar, weather, counting, good morning greetings, and a story; (b) small-group time to work on a particular skill; (c) one or two meals; (d) trips to the bathroom; and (e) an inside and outside play period. Although full-day programs do offer more hours in the day, many of the extra hours are spent in napping, toileting, and snacks. To our observers, the classrooms often felt pressured, as if teachers were racing to check off the list of things that need to be done. This kind of atmosphere does not give teachers opportunities to interact with children to talk about their lives, their play, or their ideas, nor does it provide opportunities for teachers to be responsive to children's interests and needs. Results from this study suggest that more quality instructional time spent with teachers, and less free play time spent without teacher guidance or scaffolding, would better prepare children for entering school.

In this study, 85 maltreated foster children and 56 nonmaltreated community children (*M* age = 3–6 years) were assessed across kindergarten and first grade to examine the hypothesis that inhibitory control and caregiver involvement mediate associations between a history of maltreatment and foster placement and early school adjustment. Specifically, academic and social-emotional competence were evaluated. The maltreated foster children performed more poorly in academic and social-emotional competence. Inhibitory control fully mediated the association of maltreatment and foster placement with academic competence, whereas inhibitory control and caregiver involvement mediated their association with social-emotional competence. The results suggest that inhibitory control and caregiver involvement might be promising targets for school readiness interventions for foster preschoolers.

Maltreated foster children often display difficulties in a number of cognitive and psychosocial domains (Leslie et al., 2000; Pears & Fisher, 2005), which might impinge upon success in school. Thus, it is not surprising that many of these children have scholastic difficulties, including high rates of special education placement, academic failure, and school dropout (Blome, 1997; Courtney & Dworksy, 2006; Geenen & Powers, 2006; Goerge, Van Voorhis, Grant, Casey, & Robinson, 1992; Smithgall, Gladden, Howard, Goerge, & Courtney, 2004). However, few researchers have explored how foster children fare at elementary school entry, a critical developmental milestone. In the general population, kindergarten and first-grade academic and social-emotional performance predict trajectories of school and psychosocial adjustment across later elementary and middle school grades (Duncan et al., 2007; Lesaux, Rupp, & Siegel, 2007; McClelland, Acock, & Morrison, 2006; Nagin & Tremblay, 2001). Additionally, successful adjustment in the early school years is linked to educational attainment and avoidance of psychosocial problems in adulthood (Fothergill et al., 2008). Understanding foster children's early school adjustment might be pivotal in preventing negative outcomes.

In the current study, we had two primary goals. First, we sought to explore whether disparities in school adjustment can be observed in maltreated foster children as early as kindergarten and first grade. Second, we sought to identify factors that mediate the association between a history of maltreatment and foster placement and early school adjustment.

Components of Early School Adjustment

Converging evidence suggests that successful school achievement in the early grades requires

both academic and social-emotional competence (Blair, 2002; Peth-Pierce, 2000; Raver, 2002). Early academic competence includes literacy skills such as language and reading abilities, which are predictive of later academic achievement (Duncan et al., 2007; NICHD Early Child Care Research Network, 2005). For example, Duncan and colleagues showed that early language and reading abilities positively predict achievement in reading and math up to 9 years later. Additionally, better language skills appear to serve a protective function for children exposed to risk factors that might otherwise lead to poor school adjustment (Burchinal, Roberts, Zeisel, Hennon, & Hooper, 2006). Conversely, early academic difficulties, particularly in language and reading, appear to predict trajectories of increasing academic and social-emotional problems across the school years (Chatterji, 2006; Hooper, Roberts, Zeisel, & Poe, 2003).

Social-emotional competence comprises three interrelated sets of skills: prosocial behaviors, emotion regulation, and behavior regulation. Key prosocial behaviors include the abilities to enter peer groups, to share materials with others, to cooperate, and to maintain social interactions. These skills predict positive peer and teacher relationships, which are linked to higher classroom participation and achievement (Ladd, Birch, & Buhs, 1999; Pianta & Stuhlman, 2004). Emotion regulation involves a child's abilities to modulate negative emotions (e.g., frustration) and to control positive emotions (e.g., exuberance) so that they do not disrupt academic performance and social relationships (Blair, 2002; Graziano, Reavis, Keane, & Calkins, 2007). Better emotion regulation is linked to higher academic achievement and better social skills in school within grades (Graziano et al., 2007; Howse, Calkins, Anastopoulos, Keane, & Shelton, 2003) and across grades (Newman, Noel, Chen, & Mastopoulos, 1998; Trentacosta & Izard, 2007). Behavior regulation involves a child's abilities to focus on schoolwork, to avoid disrupting classroom activities, and to make successful transitions between activities. Recent studies have linked greater behavior regulation in kindergarten and first grade to higher academic achievement concurrently (Howse, Lange, Farran, & Boyles, 2003) and longitudinally through middle school (Duncan et al., 2007; McClelland et al., 2006). Although these three components of social-emotional competence are conceptually distinct, they have been shown to be strongly intercorrelated (Graziano et al., 2007; Trentacosta & Izard, 2007).

Maltreatment and Foster Placement and Early School Adjustment

School achievement in foster children has been investigated previously (Blome, 1997; Courtney & Dworksy, 2006; Geenen & Powers, 2006; Goerge et al., 1992; Smithgall et al., 2004). However, these studies were generally concentrated on children in the middle elementary grades and higher. Few studies have been focused on foster children in early elementary school. Additionally, because these studies were generally based on archival record data, most only involved the assessment of academic functioning. A number of researchers have examined academic and social-emotional competence in maltreated children in general (e.g., Anthonysamy & Zimmer-Gembeck, 2007; Kurtz, Gaudin, Wodarski, & Howing, 1993; Veltman & Browne, 2001). This line of research is relevant to foster children because the majority of young foster children come into care due to maltreatment. However, foster children have also experienced multiple caregiver disruptions. Consequently, maltreated foster children might exhibit differences in school adjustment compared to maltreated children in general. Given the importance of adjustment at school entry to later school functioning and psychosocial outcomes (Duncan et al., 2007; Fothergill et al., 2008), understanding whether maltreated foster children show early deficits in academic and social-emotional competence is critical to the development of targeted interventions to improve school outcomes for these children.

Potential Mediational Effects on Early School Adjustment in Maltreated Foster Children

In addition to identifying maltreated foster children's deficits in early school adjustment, understanding the factors that mediate the association between a history of maltreatment and foster placement and school adjustment is essential to preventive intervention efforts. Prior research results have suggested at least two mechanisms that leave maltreated foster children vulnerable to difficulties in school: inhibitory control and caregiver involvement. Inhibitory control, a cognitive process that falls under the rubric of executive functioning, is the capacity to voluntarily inhibit or regulate prepotent attentional or behavioral responses (Casey, Tottenham, & Fossella, 2002). It has an extended developmental trajectory and changes over time from being an externally driven process to an internalized ability (Kochanska, Coy,

& Murray, 2001). Because young children are reliant on their caregivers for self-control, disruptions and inconsistencies in the early caregiving environment, such as maltreatment and foster placement, are likely to have deleterious effects on later inhibitory control. Past research findings have shown that caregiver disruptions have negative effects on inhibitory control in general and foster care populations. In a recent study of a community sample of preschool-aged children, Lengua, Honorado, and Bush (2007) found that the number of household moves predicted inhibitory control abilities. Lewis, Dozier, Ackerman, and Sepulveda (2007) showed that adopted children who had experienced multiple prior foster placements performed significantly worse on an inhibitory control task than nonadopted community children and adopted children who had experienced only one prior foster placement. Additionally, executive functions, particularly inhibitory control, have been linked to harsh parenting and maltreatment (Beers & DeBellis, 2002; Valiente, Lemery-Chalfant, & Reiser, 2007), suggesting that foster children's histories of maltreatment might also impinge on their inhibitory control.

Maltreated foster children's potential deficits in inhibitory control suggest a pathway through which maltreatment and foster placement might affect school outcomes. Prior research findings have shown that early inhibitory control is central to school success. Specifically, better inhibitory control in the preschool period has been linked to better academic and social functioning in first grade (Blair & Razza, 2007; NICHD Early Child Care Research Network, 2003). Additionally, inhibitory control appears to be positively associated with concurrent feelings of school liking in later elementary grades (Valiente, Lemery-Chalfant, & Castro, 2007). Finally, children's inhibitory control appears to partially mediate the association between family environment and children's readiness for kindergarten (NICHD Early Child Care Research Network, 2003), suggesting that inhibitory control might provide a link between early experiences and school outcomes.

Maltreated foster children are likely to be at a disadvantage in terms of another important precursor of success in school: caregiver involvement. Caregiver involvement in schooling (e.g., promotion of literacy and homework activities at home, assistance in organizing school materials, direct involvement in classroom activities, and contact with teachers and school personnel) has been shown to be a significant predictor of academic achievement across studies (Jeynes, 2005). It has been associated with higher grades, better attitudes toward schoolwork, greater participation in classroom learning activities, higher attendance rates, fewer placements into special education, fewer suspensions, and greater educational attainment over time (Barnard, 2004; Christenson, 1999).

The majority of young foster children have experienced abusive and neglectful environments in their families of origin. Although there are no prior studies of the school involvement of abusive parents, the results from one study suggest that parents might be less involved in schooling when the family is experiencing difficult life circumstances (Lamb-Parker et al., 2001). Additionally, once placed into foster care, the children often experience multiple caregiver changes. Pears and Fisher (2005) showed that preschool-aged maltreated foster children had experienced an average of 3.47 transitions. The caregiver changes associated with foster placements are likely to interfere with caregiver involvement in schooling for several reasons. First, the caregiver might not have adequate information about the child's academic history. For example, in one study, information on past academic performance was missing from 53% of foster children's school records (Parrish et al., 2001). Second, the caregiver might not have an opportunity to become involved in schooling if the child is in the home for only a limited period of time. In 2005, half of all children exiting foster care had been in their placements between 1 and 11 months (Child Welfare Information Gateway, 2007). Given the potential barriers to foster caregivers' involvement in schooling, it is not surprising that 65% of foster children in high school reported that their caregivers had never attended a teacher conference, 73% reported that their caregivers had never visited their class, and 70% reported that their caregivers had never volunteered at school (Blome, 1997). Although a limited number of studies have explored factors related to caregiver involvement in this population, caregiver involvement at school entry and its role as a mediator in the association between maltreatment and foster placement and early school adjustment have not yet been examined.

Goals of the Study

As noted earlier, the purpose of this study was two-fold. Our first goal was to explore whether deficits in school adjustment can be observed as early as kindergarten and first grade in maltreated foster children. To accomplish this, maltreated foster children were compared to nonmaltreated children living with their biological parents. We hypothesized that the maltreated foster children would exhibit lower scores on academic and social-emotional competence than their nonmaltreated peers. The second goal was to use longitudinal data to test the hypotheses that the pathways between a history of maltreatment and foster placement and poor early school adjustment (i.e., low academic and social-emotional competence) would be mediated by the following: child inhibitory control during preschool and caregiver involvement at kindergarten entry. Potential confounding variables, including the children's age and general cognitive ability, were controlled in the path model. School characteristics (e.g., socioeconomic status [SES] composition and class size) can affect school adjustment (Konstantopoulos, 2006) and were thus included in the model as control variables. Although little is known about the school contexts of foster children, one group of researchers found that foster children were less likely to attend magnet schools and were disproportionately concentrated in the lowest achieving schools (Smithgall et al., 2004).

Method

Participants

The participants in this study were a subsample of children from an efficacy trial to evaluate a treatment foster care program for preschool-aged children. The entire sample included a foster care (FC) group of 117 maltreated foster children and a community comparison (CC) group of 60 age- and SES-matched, nonmaltreated children living with their biological families. For the FC group, children between the ages of 3 and 6 entering new foster placements were referred to the study through the local child welfare system. The inclusion criteria for the FC group specified placement in a nonrelative foster home, an expectation of remaining in foster care for at least 3 months, and English as the primary language of the child and foster caregiver. A staff member contacted each child's caseworker (the legal guardian while the child is in care) and requested consent for the child to participate in the study. Upon receiving caseworker consent, a staff member then contacted the foster caregiver to invite him or her to participate. For a child to be successfully recruited, the caseworker and foster caregiver had to consent to participate.

The CC group was recruited via flyers posted at local supermarkets, day-care centers, and Head Start classrooms and through advertisements in local newspapers and newsletters. The CC families were included in the study if the child had lived consistently with at least one biological parent, household income was no more than $30,000, parental education level was less than a 4-year college degree, and the family had no prior involvement with the child welfare system.

The FC and CC children were 3–6 years old when they were recruited to participate in the study for a period of 24 months. Because the mean age of the children at the baseline assessment was 4.46 years ($SD = 0.81$), most children were not in school at study entry. Data on performance in kindergarten and first grade were collected for 85 FC and 56 CC children who were still participating in the study when they entered those grades. Of the 36 children (32 FC and 4 CC) for whom school data were not available, 28 (26 FC and 2 CC) discontinued their participation in the study before they entered school, 5 were too young to have entered school by the end of the 24-month assessment period (4 FC and 1 CC), 2 were homeschooled (1 FC and 1 CC), and 1 FC child was in second grade by the time that school data were collected. Children for whom school data were not available did not differ significantly on age, sex, ethnicity, or general cognitive functioning from those for whom the data were available.

Although all 85 FC children were in foster care at study entry, 12 children had been permanently placed with biological relatives, and 8 children had been adopted by nonrelatives when the school assessments were conducted. There were no differences between these children and the other FC children on any of the study variables; thus, all children were retained in the FC group. As noted earlier, all FC children were part of a larger efficacy trial to evaluate a treatment foster care program (Multidimensional Treatment Foster Care for Preschoolers; Fisher, Gunnar, Chamberlain, & Reid, 2000) and were assigned to intervention or comparison groups at study entry. (The CC children were not randomized to different conditions.) Maltreated foster children from the intervention ($n = 45$) and control ($n = 40$) groups were combined in the present sample because there were no mean differences between the two groups on any of the variables used in the present study (either the individual scores or the composites) and because correlational analyses with treatment status as a covariate did not reveal any experimental effects.

The FC and CC groups did not differ on mean child age, gender, or ethnicity. Mean age at the first school assessment was 5.89 years ($SD = 0.47$) in the

FC group and 5.81 years (*SD* = 0.49) in the CC group. Boys comprised 53% of the FC group and 54% of the CC group. The ethnicity breakdown of the FC group was: 85% European American, 1% African American, 8% Latino, and 6% Native American. The ethnicity breakdown of the CC group was: 79% European American, 5% African American, 7% Latino, 7% Native American, and 2% Pacific Islander. The study included 22 sibling dyads (12 FC and 10 CC) and 3 sibling tetrads (3 FC).

The FC children had experienced an average of 1.84 placements, 3.73 transitions between placements, and 164 days in care prior to study entry. All FC children had histories of maltreatment. Child welfare case records coded using the Maltreatment Classification System (Barnett, Manly, & Cicchetti, 1993) revealed that the children had experienced physical abuse (36%), sexual abuse (27%), physical neglect (81%), supervisory neglect (87%), and emotional maltreatment (89%). No CC children had been reported for child maltreatment by study entry (as verified by a search of child protective service records).

Procedure

As noted earlier, the children entered the study between 3 and 6 years of age and participated in the study for 24 months. If the children entered school during the time that they participated in the study, school data were collected in the fall and spring of their kindergarten year and in the spring of their first-grade year. Some of the children had attended kindergarten and first grade by the end of the 24 months and participated in all school assessments. Some children, however, were young enough at study entry that they participated only in the kindergarten assessments, whereas some children were old enough at study entry that they participated only in the kindergarten spring assessment, the first-grade assessment, or both. Thus, not every child had data for all school assessment points. One hundred twenty-five children (89%) had data for the kindergarten fall assessment, 107 (76%) had data for the kindergarten spring assessment, and 96 (68%) had data for the first-grade spring assessment. Sixty-nine children (49%) participated at all three assessment points, 49 children (35%) participated at two assessment points, and 23 children (16%) participated at one assessment point. To maximize the number of children included in the analyses and the data available for each child, measures were combined across the kindergarten and first-grade assessments.

In addition to the school assessments, all children and their families completed laboratory-based measures and questionnaires at 3-month intervals over the 24 months of the study. At the baseline assessment (study entry), the children completed laboratory-based measures to assess inhibitory control and general cognitive functioning. At the 3-month assessment, the caregivers completed a questionnaire measure of inhibitory control. Because the children entered the study at different ages, the time between the baseline assessment and the first school assessment varied (*M* = 17 months, *SD* = 9 months).

For the current study, individual scales and multimethod, multiagent composites were created according to Patterson and Bank's (1986) method and were examined in analyses. All scales and composites had to show an internal reliability of .60 or higher (standardized alpha), and all items in a scale or composite had to show an item–total correlation of .20 or higher.

Group Status

In the current study, a history of maltreatment and foster placement was represented by a dichotomous variable. The FC children were coded as 1 (*history of maltreatment and foster placement*), whereas the CC children were coded as 0 (*no history of maltreatment or foster placement*).

School Adjustment

Academic Competence

This aspect of school adjustment was assessed via a composite measure of teacher report and school records data. Teachers rated the children's performance in language, language comprehension, articulation, and self-help abilities on a scale of 1 (*superior*) to 5 (*delayed*) as a measure of the children's language and learning skills. The scores were reverse coded: Higher scores indicated higher skill. The language and learning skills scale showed good internal consistency at all school assessments. Reliability information for all school adjustment measures across time is shown in Table 1. Additionally, we collected information from school records on the number of special academic services received during kindergarten and first grade. These special services were classified according to the following categories: special education in the general classroom, special education in a self-contained classroom, and Chapter I/Title I services. The number

Table 1
Reliability Statistics for Subscales of the School Adjustment Measures

	Kindergarten fall	Kindergarten spring	First-grade spring
Language and learning skills	.87	.90	.84
Prosocial behavior	.90	.89	.91
Emotion regulation (r values)	.41	.48	.60
Behavior regulation	.82	.78	.79

Note. All values represent standardized alpha coefficients unless otherwise noted.

of special academic services was reverse scored. The language and learning skills scales were combined across time points ($\alpha = .77$), as were the numbers of special academic services received ($r = .35$, $p < .05$). The resulting language and learning skills and number of academic services scores were significantly correlated ($r = .51$, $p < .001$), and these scores were standardized and combined to produce the academic competence composite score. Higher values represent better academic competence.

Social-Emotional Competence

This composite score was composed of three domain scores—prosocial behaviors, emotion regulation, and behavior regulation—and was assessed using four teacher-report measures and one child-report measure. The Teacher Social Competence Scale (Conduct Problems Prevention Research Group, 1995) is a 12-item measure that assesses children's prosocial behavior and communication skills and emotion regulation. The Loneliness and Social Dissatisfaction Questionnaire for Young Children–Teacher Version (Cassidy & Asher, 1992) is a 12-item instrument designed to assess child behavior on four dimensions: aggression, disruptiveness, prosocial behavior, and withdrawal. The Walker-McConnell Scales of Social Competence and School Adjustment (Walker & McConnell, 1988) is a 45-item teacher-report instrument measuring teacher-preferred behaviors, peer-preferred behaviors, and school adjustment. The teachers also completed the Emotion Regulation Checklist (Shields & Cicchetti, 1997), a 27-item questionnaire that measures emotion regulation and lability and negativity. The children completed the Seattle Personality Questionnaire (Greenberg & Lengua, 1995), a 44-item measure that forms eight subscales, including the Conduct Problems subscale.

Prosocial behavior. This score comprised three scales: the six-item Prosocial Behaviors/Communication Skills subscale of the Teacher Social Competence Scale, the three-item Prosocial Behaviors subscale of the Loneliness and Social Dissatisfaction Questionnaire for Young Children–Teacher Version, and the 17-item Peer-Preferred Behaviors subscale of the Walker-McConnell Scales of Social Competence and School Adjustment. At each time point, the individual scales were standardized and averaged to form the prosocial behavior domain score (see Table 1). These scores were then averaged across time points ($\alpha = .78$).

Emotion regulation. This score comprised two scales: the six-item Emotion Regulation subscale of the Teacher Social Competence Scale and the eight-item Emotion Regulation subscale of the Emotion Regulation Checklist. The scales were significantly positively correlated at each time point (see Table 1). Thus, the scales were standardized and averaged at each time point and then averaged across time points ($\alpha = .80$).

Behavior regulation. This score comprised four subscales: the three-item Aggression and three-item Disruptiveness subscales of the Loneliness and Social Dissatisfaction Questionnaire for Young Children–Teacher Version, the 15-item Lability/Negativity subscale of the Emotion Regulation Checklist, and the eight-item Conduct Problems subscale of the Seattle Personality Questionnaire. Within each time point, the scales were standardized and averaged, producing internally consistent domain scores (see Table 1). These scores, which were averaged across time points ($\alpha = .83$), were reverse scored: Higher scores reflected better behavior regulation.

The goal in producing separate social-emotional domain scores was to use the individual scores in the analyses. However, in preliminary analyses, the domain scores showed strong associations with one another ($rs = .75$–$.92$). To avoid problems of multicollinearity in the analyses, the prosocial behaviors, emotion regulation, and behavior regulation domain scores were averaged to produce an overall social-emotional competence composite score. The composite showed high internal consistency ($\alpha = .96$).

Mediators of the Effects of Maltreatment and Foster Placement on School Adjustment

Inhibitory Control

Inhibitory control was assessed via laboratory child assessments and caregiver reports. The laboratory assessments included the modified Stroop task (Gerstadt, Hong, & Diamond, 1994), which is associated with other measures of inhibitory control (Carlson & Moses, 2001). The children were instructed to say "night" whenever they saw a card with a yellow sun on a white background and to say "day" whenever they saw a card with a white moon on a black background. Sixteen cards were presented in a pseudorandom order. The mean correct score was used in analyses. Children also completed the Dimensional Change Card Sort task (adapted from Frye, Zelazo, & Palfai, 1995), which correlates well with other inhibitory control measures (Carlson & Moses, 2001). In this task, the children were asked to sort a series of cards first according to one criterion and then according to another criterion, which required inhibition of the tendency to respond according to the first criterion. For three of the postswitch trials (after the sorting criterion changed), the cards were incompatible with the preswitch rules. The mean correct score for the incompatible trials was used in analyses. The attention/executive function domain of the NEPSY (Korkman, Kirk, & Kemp, 1998) was also used. For 3- and 4-year-olds, this domain includes two subscales: Visual Attention and Statue. (The NEPSY was not administered to children who were over the age of 5 at the baseline assessment [$n = 40$]; thus, this score was not included in the composite for these children.) The caregiver reports were assessed using the Inhibitory Control and Attention Focusing scales of the Children's Behavior Questionnaire (Rothbart, Ahadi, Hershey, & Fisher, 2001), which assess behavior and attention regulation, respectively. The laboratory measures and caregiver ratings were standardized and averaged to form the inhibitory control composite ($\alpha = .68$).

Caregiver Involvement in Schooling

Caregiver involvement in schooling was assessed in the fall of the kindergarten year via a nine-item, teacher-report scale measuring caregiver involvement in preparing children for school, the frequency of caregiver communication with the teacher, and caregiver interest in solving problems at school. The scale showed good internal consistency ($\alpha = .89$).

Covariates

General Cognitive Functioning

At the baseline assessment, the children completed the Vocabulary and Block Design subtests of the Wechsler Preschool and Primary Scale of Intelligence–Revised (WPPSI–R; Wechsler, 1989). These subtests are considered to be the strongest measures of verbal and performance intelligence, respectively, and are highly correlated with other general intelligence measures (Wechsler, 1989). The scaled scores for these subtests were averaged. In the general population, the mean of WPPSI–R scaled scores is 10 ($SD = 3$).

Age at the Baseline Assessment

Because inhibitory control is associated with age (Kochanska, Murray, & Harlan, 2000), we controlled for age at the baseline assessment in all analyses. Additionally, as noted earlier, the time between the baseline assessment and the first school assessment varied. However, child age at the baseline assessment was strongly correlated with time between the baseline and school assessments ($r = -.81$, $p < .001$). Rather than adding another control variable, we used child age at the baseline assessment to control for time between the baseline and school assessments.

School Characteristics

Indices of school characteristics were retrieved from the Oregon State Department of Education's Web site (e.g., number of children receiving free or reduced lunches, average class size, and percentage of teachers with a master's degrees or higher; Oregon Department of Education, 2007). These indices were averaged across kindergarten and first grade. These data were not available at either kindergarten or first grade for 7 children: 3 children in private schools (1 FC and 2 CC), 3 FC children in specialized schools, and 1 CC child living out of state. Additionally, each child's school was classified as a regular public school, a private or magnet school, or a specialized treatment school. In a few cases, a child attended a regular school for 1 year and a private or magnet school the other year; in such instances, the child was coded as attending a private or magnet school. No children had been in a private or magnet or regular school and a specialized treatment school.

Data Analysis Plan

Preliminary analyses were conducted to examine patterns of normality and missing data. Next, differences between the FC and CC groups on the hypothesized mediators, covariates, and outcomes were examined using Hotelling's T^2 tests to control for inflated error rates. This was followed by tests of the associations between the hypothesized mediators, covariates, and outcomes using bivariate correlations. Finally, the full path model with the hypothesized mediators, covariates, and outcomes was tested using Mplus (Version 5.1; Muthén & Muthén, 2007).

Results

Preliminary Analyses

Prior to the analyses, all variables were examined for significant deviations from normality and outliers. The caregiver involvement variable was significantly skewed and was log-transformed. Additionally, for the academic and social competence variables, there was one extreme outlier for each (±3 *SD* of the mean). These scores were recoded to the next value that was within 3 *SD* of the sample mean. In general, for the composite scores and other variables, there were few missing data (< 6%), with the exception of caregiver involvement. Because caregiver involvement in the fall of the kindergarten year was used, missed assessments at this time point resulted in data missing for 17% of the sample on this variable. In the path analyses using Mplus, missing data were estimated using full information maximum likelihood techniques. To account for the nonindependence of the sibling groups, the Hotelling's T^2 tests and bivariate associations were repeated with randomly selected siblings omitted. There were no significant changes in the patterns of results. Additionally, the cluster design approach in Mplus, which adjusts standard errors for the nonindependence of data, was used for the path analyses. Thus, to maximize power, all siblings were retained in the analyses. Finally, to determine if there were gender differences on the hypothesized mediators, covariates, and outcomes, gender was entered into the Hotelling's T^2 tests. The overall T^2 values were not significant. Thus, gender was not included as a covariate.

Group Differences

To control for the possibility of inflated errors with multiple single *t* tests, two Hotelling's T^2 tests were used to examine group differences. The hypothesized mediators, covariates, and outcomes were tested in two groups: one included the child and family characteristics (mediators, general cognitive ability, and school adjustment) and the other included the school characteristics variables. The overall T^2 statistic (adjusted for unequal covariances) for the child and family characteristics indicated that there were significant group differences, $T^2(5, 103) = 33.51$, $p < .01$. As shown in Table 2, follow-up individual *t* tests indicated that the groups differed on all variables. (Negative values on composite scores indicate that the scores were below the sample mean.)

Table 2

Means and Standard Deviations by Groups for the Hypothesized Mediators, Covariates, and Outcomes

	Foster care group		Community comparison group		
	M	*SD*	*M*	*SD*	*t*
School outcome measures					
Academic competence	−0.16	0.92	0.30	0.67	2.93**
Social-emotional competence	−0.21	0.70	0.25	0.73	3.42**
Hypothesized mediators					
Inhibitory control	−0.11	0.69	0.28	0.53	3.28**

Percentage of students receiving free or reduced lunch	52.51	16.89	46.60	17.05	1.96†
Average class size	23.31	2.28	23.33	1.53	0.07
Percentage of teachers with a master's degree or higher	45.87	13.10	52.94	13.99	2.96**
General cognitive ability	8.02	2.14	9.80	2.06	4.42**
Age at the baseline assessment	4.54	0.82	4.33	0.79	1.51

Note. Negative values on composite scores indicate that the scores were below the sample mean.
†$p < .10$. **$p < .01$.

For the school characteristics, there was a significant overall T^2 statistic (adjusted for unequal covariances), $T^2(3, 106) = 12.36$, $p < .01$. Examination of the individual t tests revealed that there was a significant group difference in the percentage of teaching staff with a master's level degree or higher (Table 2).

Finally, a chi-square test was used to determine if there were group differences in the likelihood of attending private or magnet schools. In the current study, 25% of the CC children attended a private or magnet school compared to 6% of the FC children, $\chi^2(1) = 10.58$, $p < .01$. (The group difference remained even when the 5 FC children in treatment schools were excluded from analyses.)

Correlational Analyses

The bivariate correlations among the variables are displayed in Table 3. Consistent with the group differences, a history of maltreatment and foster placement was associated with lower academic and social-emotional competence in kindergarten and first grade. It was hypothesized that inhibitory control in preschool and caregiver involvement in kindergarten would mediate the associations between a history of maltreatment and foster placement and school adjustment in kindergarten and first grade. To meet the criteria for mediation, the hypothesized mediators needed to be significantly associated with the predictor and outcome variables (Baron & Kenny, 1986). This proved to be the case for inhibitory control, which was significantly negatively associated with a history of maltreatment and foster placement and significantly positively associated with the school adjustment measures. Also in accordance with predictions, caregiver involvement in school was significantly negatively associated with a history of maltreatment and foster placement and significantly positively associated with academic and social-emotional competence.

The associations among the covariates and the other measures were also examined. As detailed earlier, there were moderate correlations between some school characteristic variables and a history of maltreatment and foster placement; however, these variables were not significantly associated with the mediators or the outcomes. Thus, these variables were not used as covariates in the path analyses described next. General cognitive ability was strongly associated with academic competence and less strongly (but significantly) associated with social-emotional competence. Additionally, general cognitive ability and age at the baseline assessment were significantly positively associated with inhibitory control.

Path Analysis

Mplus was used to conduct the path analyses to determine whether the patterns of associations between a history of maltreatment and foster placement and the hypothesized mediators and outcomes remained significant when age and general cognitive ability were controlled. Additionally, the significance of mediated paths was tested. The results of the path analysis, trimmed to show only paths with a probability level of .10 or less, are shown in Figure 1. (The patterns of significance did not differ from those in the full, nontrimmed model, which was not a significantly better fit than the model presented here.) The trimmed model

$^\dagger p < .10$. $^*p < .05$. $^{**}p < .01$.

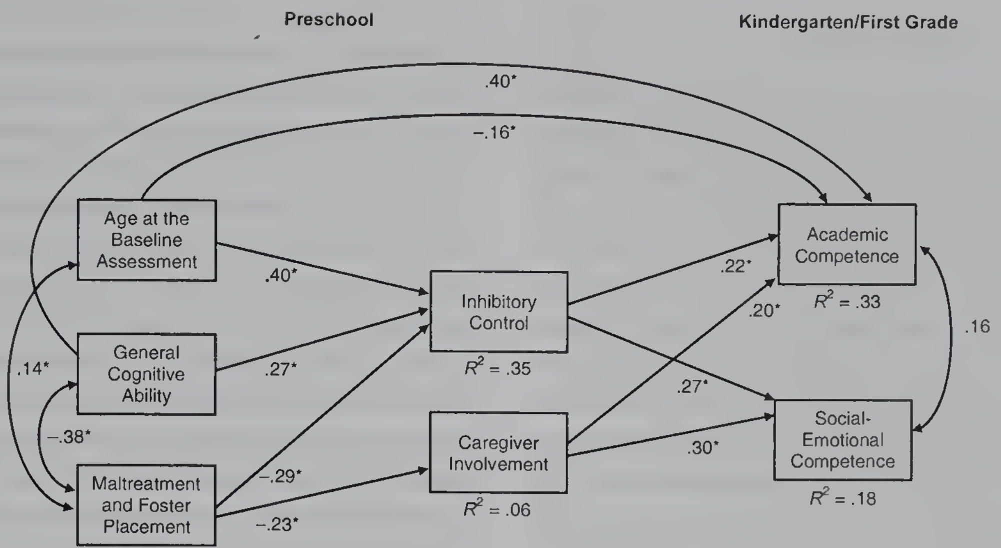

Figure 1. Path analysis of the associations between a history of maltreatment and foster placement, hypothesized mediators, covariates, and school adjustment.
$^*p < .05$.

showed a good fit, $\chi^2 = 8.84$, $p = .36$, comparative fit index (CFI) = .99, Tucker-Lewis index (TLI) = .99, root mean square error of approximation (RMSEA) = .000, standardized root mean square residual (SRMR) = .05. As was hypothesized, although a history of maltreatment and foster placement was significantly related to academic and social-emotional competence in the bivariate correlations, it was not in the full model. Direct paths between a history of maltreatment and foster placement and the school adjustment variables did not reach significance. Instead, as was predicted, the effects of a history of maltreatment and foster placement on academic and social-emotional competence were fully mediated through inhibitory control. The indirect path from a history of maltreatment and foster placement to academic competence through inhibitory control was significant ($t = -2.08$), as was the indirect path from a history of maltreatment and foster placement to social-emotional competence through inhibitory control ($t = -2.74$).

Additionally, there was a significant indirect path from a history of maltreatment and foster placement to social-emotional competence through caregiver involvement ($t = -2.10$). This finding supports the hypothesis that the effects of a history of maltreatment and foster placement on social-emotional competence are mediated through caregiver involvement. There was also a significant association between caregiver involvement and academic competence, although the indirect path from a history of maltreatment and foster placement to academic competence through caregiver involvement was not significant.

In the model, general cognitive ability was no longer directly associated with social-emotional competence. Instead, there was a significant indirect path from general cognitive ability to social-emotional competence through inhibitory control ($t = 2.38$), indicating full mediation. Age at the baseline assessment was significantly negatively associated with academic competence, suggesting that children who entered the study at younger ages demonstrated better academic competence.

To examine whether there were different patterns of associations within the FC and CC groups, a multiple groups model was run. The patterns of associations were similar across the two groups with two exceptions: General cognitive ability was not associated with inhibitory control in the CC group, and age at the baseline assessment was not associated with academic competence in the CC group. Also, because the FC and CC groups differed significantly on general cognitive ability (with a 1.78 point mean difference equal to .60 of a standard deviation, or about 9 IQ points), additional analyses were undertaken to determine if the group differences in school adjustment might be attributable to differences in general cognitive ability. Although the group means differed significantly, there was also considerable overlap between the two groups, allowing for exact matching of 40 FC children with 40 CC children on general cognitive ability scores. The path model described earlier was then rerun with only those 80 children. Although significance was in some cases reduced due to the smaller sample size, the patterns of associations were the same as those found in the path analysis that included the whole sample with general cognitive ability as a covariate.

Discussion

Maltreated foster children are at high risk for difficulties in school adjustment (Blome, 1997; Courtney & Dworksy, 2006; Geenen & Powers, 2006; Goerge et al., 1992; Smithgall et al., 2004). The current study demonstrates that these difficulties are apparent as early as school entry. Compared to their nonmaltreated peers, maltreated foster children showed lower academic and social-emotional competence in kindergarten and first grade. This finding was not surprising given that preschool-aged foster children show deficits in a number of domains such as language, psychosocial functioning, and neuropsychological functioning (Klee, Kronstadt, & Zlotnick, 1997; Pears & Fisher, 2005; Stahmer et al., 2005). However, this is the first study to focus on the functioning of maltreated foster children at school entry. The finding that maltreated foster children demonstrate deficits in the early school years underscores the significance of screening preschool-aged foster children for developmental delays. Additionally, the results from this study suggest that, in the absence of prior screening, foster children might need to be screened upon school entry for academic and social-emotional difficulties to enable timely intervention.

Preschool levels of inhibitory control were positively associated with academic and social-emotional competence in kindergarten and first grade. This finding provides further support for the hypothesis that inhibitory control abilities are important components of school readiness (McClelland et al., 2006) and is consistent with other studies linking inhibitory control with greater school readiness skills (e.g., Blair & Razza, 2007). As noted earlier, children who show greater inhibitory control are able to regulate prepotent behavioral and attentional responses. Thus, they are more likely to focus on academic activities. They are also more likely to control their behavioral responses to peers and to show more prosocial behavior.

Inhibitory control was negatively associated with a history of maltreatment and foster placement, suggesting that these experiences have deleterious effects on this ability. This is consistent with other studies showing that early parenting and family environment shape the development of inhibitory control in the toddler and preschool years (Kochanska et al., 2000; Valiente, Lemery-Chalfant et al., 2007). Specifically, this association supports findings from other populations of children who have experienced early adversity. As noted earlier, other studies have demonstrated negative effects of maltreatment and multiple foster placements on inhibitory control (Beers & DeBellis, 2002; Lewis et al., 2007). Researchers working with postinstitutionalized adoptees who experienced severe deprivation have shown that these children also display deficits in attentional processes in general (Kreppner, O'Connor, Rutter, & the English and Romanian Adoptees Study Team, 2001) and in inhibitory control specifically (Bruce, Tarullo, & Gunnar, 2009). Thus, this finding is consistent with previous results suggesting that early adversity has significant neurobiological consequences. By and large, these studies have not yet disentangled the effects of maltreatment and multiple caregiver disruptions. This remains an important topic for future research.

These neurobiological effects of early adversity might impact longer term outcomes given that the effects of a history of maltreatment and foster placement on school adjustment a number of years later were fully mediated by preschool inhibitory control. Although these results illustrate the potential long-term developmental consequences of maltreatment and foster placement, they also suggest a potentially powerful avenue for preventive intervention. Helping maltreated foster children to improve their inhibitory control skills prior to kindergarten might help to prevent academic and social difficulties and, in turn, place the children on a track of increasing school success. A recent school-based preventive intervention program aimed at reducing behavioral problems and promoting social-emotional competence was shown to improve inhibitory control abilities in elementary school children (Riggs, Blair, & Greenberg, 2003), suggesting that inhibitory control abilities are amenable to intervention efforts.

The results from this study also support the importance of increasing caregiver involvement in schooling as a means of promoting maltreated foster children's positive school adjustment. As with inhibitory control, caregiver involvement fully mediated the effects of a history of maltreatment and foster placement on social-emotional competence. Foster caregivers were less involved in children's schooling than were the biological parents of the nonmaltreated children. As noted earlier, this disparity might be due to a number of factors including the foster caregiver's lack of information about the child's school history and the relatively short duration of foster placements. Additionally, foster caregivers might not be aware of the processes that govern access to special services and might be unsure about whether they can authorize the children's participation in them (Choice et al., 2001). Thus, foster caregivers might benefit from additional education about the needs of foster children and ways to make contact with school personnel and to obtain services for the children.

Inhibitory control and caregiver involvement are not likely to be the only mediators in the association between a history of maltreatment and foster placement and school outcomes. Other factors such as developmental status, language abilities, and early literacy skills are likely to impact foster children's success in early elementary school. However, the findings of the current study suggest that interventions that include foci on inhibitory control skills and caregiver involvement in schooling, along with emphases on early literacy skills to increase academic competence and social-emotional skills to enhance social competence, might be particularly effective in improving maltreated foster children's early school adjustment. Head Start, one of the most widely recognized school readiness interventions, is focused on children's early literacy and social-emotional skills and caregiver involvement in school (Zigler & Styfco, 1995). This groundbreaking program has been found to increase literacy and social skills in low-income children (Abbott-Shim, Lambert, & McCarty, 2003; U.S. Department of Health and Human Services, 2001). More recently, several promising programs with foci on social-emotional skills and behavior regulation have shown positive impacts on children's social skills and behaviors (Domitrovich, Cortes, & Greenberg, 2007; Webster-Stratton, Reid, & Stoolmiller, 2008). Although these programs have demonstrated efficacy with general populations of children, none has been tested specifically with maltreated foster children, and none offers all components that seem to be important for these children. For example, although Head Start is focused on early literacy skills, social-emotional skills, and caregiver involvement, it lacks a focus on improving inhibitory control. Conversely, programs aimed at increasing behavior regulation are not focused on caregiver involvement. Thus, perhaps programs that emphasize inhibitory control and caregiver involvement as well as early literacy skills and social-emotional skills will be more efficacious in improving the school readiness of maltreated foster children (Pears, Fisher, & Bronz, 2007; Pears, Fisher, Heywood, & Bronz, 2007).

In the current study, it was surprising that school characteristics did not appear to be related to outcomes in correlational analyses. Other researchers have found such factors to be associated with school adjustment (Konstantopoulos, 2006). The maltreated foster children and their nonmaltreated peers were matched on SES, and the schools in the metropolitan area in which this study was conducted were all relatively well ranked. Thus, the schools might have been too homogeneous to detect the effects of school characteristics on outcomes. Future researchers should explore how school quality might help maltreated foster children to compensate for deficits in academic and social-emotional skills.

In this study, we identified two important mediators between a history of maltreatment and foster placement and early school adjustment. However, a few limitations and directions for future research should be noted. First, although the sample included a relatively large number of maltreated foster children and the effects of the mediators were moderate, the sample size might have limited the power to detect weaker associations among variables. The smaller sample size also precluded examining the effects of specific dimensions of maltreatment and foster care experiences (e.g., type of maltreatment and number of caregiver transitions) on the mediators and school outcomes. As noted earlier, maltreated foster children are unique because they have been maltreated and placed into foster care. Thus, future work should focus on disentangling the effects of specific maltreatment and foster care experiences. Additionally, as noted earlier, although inhibitory control and caregiver involvement appear to be important mediators of the association between a history of maltreatment and foster placement and later school adjustment, they are not likely to be the only ones. Future researchers should focus on identifying additional mediators that would provide further targets for preventive interventions. Finally, there were no gender differences in the outcomes or mediators in the current sample. Using a subsample of the children in the current study, Leve, Fisher, and DeGarmo (2007) found that gender moderated the association between foster care status and peer relations in the early grades. However, that study focused exclusively on measures of peer relations rather than on broader measures of social-emotional competence.

The findings from the current study demonstrate that maltreated foster children are markedly behind their peers in academic and social-emotional competence as early as kindergarten and first grade. In the absence of intervention, these deficits are likely to lead to maladaptive trajectories of academic achievement across the school years. There is cause for hope, however, in the identification of two possible targets for preventive intervention: inhibitory control and caregiver involvement. Interventions that target inhibitory control and caregiver involvement as well as early literacy and social-emotional skills might place the maltreated foster children on increasingly positive trajectories of academic and social success.

On the Progression and Stability of Adolescent Identity Formation: A Five-Wave Longitudinal Study in Early-to-Middle and Middle-to-Late Adolescence

This study examined identity development in a 5-wave study of 923 early-to-middle and 390 middle-to-late adolescents thereby covering the ages of 12–20. Systematic evidence for identity progression was found: The number of diffusions, moratoriums, and searching moratoriums (a newly obtained status) decreased, whereas the representation of the high-commitment statuses (2 variants of a [fore]closed identity: ''early closure'' and ''closure,'' and achievement) increased. We also found support for the individual difference perspective: 63% of the adolescents remained in the same identity status across the 5 waves. Identity progression was characterized by 7 transitions: diffusion → moratorium, diffusion → early closure, moratorium → closure, moratorium → achievement, searching moratorium → closure, searching moratorium → achievement, and early closure → achievement.

Erikson (1968) theorized that one of the main tasks for adolescents is to develop a coherent sense of identity. Marcia's (1966) identity status model has been one of the most important, and widely studied and utilized, elaborations of Erikson's views on identity formation. Marcia distinguished four identity statuses based on the amount of exploration and commitment the adolescent is experiencing or has experienced. Identity diffusion (D) indicates that the adolescent has not yet made a commitment regarding a specific developmental task and may or may not have explored among different alternatives in that domain. Foreclosure (F) signifies that the adolescent has made a commitment without much prior exploration. In moratorium (M), the adolescent is in a state of active exploration and has not made significant commitments. Identity achievement (A) signifies that the adolescent has finished a period of active exploration and has made a commitment based on this exploration. Notably, Waterman (1982) has proposed that adolescents move from diffusion toward achievement as they progress through adolescence. This study was designed to test this developmental interpretation of the identity status model: Are identity statuses stable individual dispositions or do they change over time? We used a five-wave longitudinal data set to study identity formation from early to late adolescence (ages 12–20).

Identity Statuses: Individual Differences or Development?

In his original contribution, Marcia (1966) conceptualized the identity statuses in terms of individual differences: ''as individual styles of coping with the psychosocial task of forming an ego identity'' (p. 558). In this sense, the statuses represent different individual states or dispositions. Most identity researchers have adopted this perspective and view the statuses as stable individual dispositions. However, some writers have proposed that the statuses constitute a developmental sequence.

This study was supported by grants to Wim Meeus and Susan Branje from the Netherlands Organization for Scientific Research (NWO).

Indeed, Waterman (1982) proposed a "developmental hypothesis" of the identity status model. This hypothesis involves two assumptions: First, the development of identity has a direction: development represents "changes in identity status that constitute progressive developmental shifts" (Waterman, 1982, p. 343). Such progressive development involves a movement away from diffusion and toward achievement. The second assumption is that progressive development also involves a specific pattern of transitions between identity statuses: from diffusion into foreclosure or moratorium, and from foreclosure and moratorium into achievement. Consequently, Waterman assumes that adolescents starting from diffusion move through foreclosure or moratorium and then into achievement. Most prominent among the identity transitions that Waterman proposes are D → M or D → F, F → M, and M → A.

Overviews of studies using identity status classifications have offered limited, but consistent, support for the first assumption within Waterman's (1982) developmental hypothesis. Meeus (1996) reported that in 17 of 25 studies reviewed, the prevalence of achievers was higher in the older age groups, and the prevalence of diffusions was higher in the younger age groups. In their reviews, both Van Hoof (1999) and Berzonsky and Adams (1999) found progressive developmental trends in 7 of 14 longitudinal studies, and across studies they found a higher prevalence of progressive than regressive shifts. Findings also revealed that, across studies, more than half of participants remained in the same identity status during the course of the study. In a recent meta-analysis of cross-sectional and longitudinal studies, Kroger (2007) found the prevalence of achievements to be about 1.5 times higher in emerging adults (ages 22–29) as compared to middle adolescents (aged 15), and the prevalence of diffusions to be about 1.3 times lower.

Support for Waterman's (1982) second assumption is very scarce. A limited number of longitudinal studies (Adams & Fitch, 1982; Dellas & Jernigan, 1987; Kroger, 1988; Meeus, Iedema, Helsen, & Vollebergh, 1999; Waterman, Geary, & Waterman, 1974; Waterman & Goldman, 1976; Waterman & Waterman, 1971) have tested whether transitions out of some statuses (e.g., diffusion) are more prevalent than transitions into those statuses. The available findings suggest that in cases where adolescents do change statuses, more adolescents move out of diffusion than into it (in about 30% of the studies), more into than out of achievement (in about 50% of the studies), more out of than into foreclosure (in about 22% of the studies), and more out of than into moratorium (in about 29% of the studies). Over-time stability of the identity statuses was 59%. These patterns suggest that identity status is more likely to remain stable than to change, and that when change does occur, this change tends to be reflected in movement out of diffusion, foreclosure and moratorium, and into achievement.

These findings are not inconsistent with Waterman's (1982) second assumption, but they also suggest that the assumption has yet to be subjected to rigorous empirical test. A full test requires that identity status changes are simultaneously tested in a transition table that incorporates all possible transitions between identity statuses; in a two-wave study with four identity statuses, this would require a test of a 4 × 4 transition matrix. The studies cited earlier only tested whether the number of movers into each status was different from the movers out of that status. As a result, systematic empirical tests of the sequential patterns of identity status transitions that Waterman hypothesized remain to be conducted, for instance, that the chances for the transition from diffusion to moratorium are greater than for the transition from diffusion to achievement.

The major aim of this study is therefore to provide a systematic account of identity status transitions—both progressive and regressive—over time. The prevalence of transitions will also provide information regarding the extent to which identity statuses represent stable individual dispositions or change over time. We now proceed to presenting our conceptualization of identity formation, in terms of the processes that underlie the identity statuses.

A Dimensional Approach: Commitment, In-Depth Exploration, and Reconsideration

Our approach focuses on the management of commitments and posits three dimensions as underlying the process of identity formation. *Commitment* refers to strong choices that adolescents have made with regard to various developmental domains, along with the self-confidence that they derive from these choices. *In-depth exploration* represents the ways in which adolescents maintain their present commitments. It refers to the extent to which adolescents actively explore the commitments that they have already made by reflecting on their choices, searching for information about these commitments, and talking with others about them. *Reconsideration of commitment* refers to the willingness to discard one's commitments and to search for new commitments. Reconsideration refers to the comparison of present commitments with possible alternative commitments when the present ones are no longer satisfactory.

Our model assumes that identity is formed in a process of continuous interplay between commitment, in-depth exploration, and reconsideration. Our model holds that individuals enter adolescence with a set of commitments of at least minimal strength in important ideological and interpersonal identity domains, and that adolescents do not begin the identity development process with a ''blank slate.'' The initial commitments build upon the way in which adolescents have resolved the earlier Eriksonian psychosocial crises in childhood and have developed the ego strengths of hope, will, purpose and competence (Erikson, 1968). Numerous studies have offered support for these assumptions. Markstrom, Sabino, Turner, and Berman (1997) and Markstrom and Marshall (2007) found clear links between previous Eriksonian ego strengths and identity achievement. Moreover, a number of studies have suggested that early adolescents can possess strong identity commitments (Adams & Jones, 1983; Archer, 1982; Meeus et al., 1999).

During adolescence, individuals manage their commitments in two ways: through in-depth exploration and through reconsideration. In-depth exploration is a process of continuous monitoring of present commitments and serves the function to make them more conscious and to maintain them. Reconsideration is the process of comparing present commitments to alternative ones and deciding whether they need to be changed. Our model therefore focuses on the dynamic between certainty (exploration in depth) and uncertainty (reconsideration).

So, our model differs from Marcia's (1966) model in two respects. First, it differentiates Marcia's concept of exploration into in-depth exploration and reconsideration, which serve to maintain and change commitments, respectively. Second, our model has a stronger process orientation than Marcia's model. Marcia views commitments as the outcome of the process of exploration: After exploring various alternative commitments, adolescents choose one or more to which they will adhere. In contrast, our model assumes, as suggested by Grotevant (1987, p. 214), that commitments are formed and revised in an iterative process of choosing commitments and reconsidering them. In addition, our model assumes that adolescents regularly reflect upon their present commitments. In sum, our conceptualization of the process of identity formation implies a twofold management of present commitments. This conceptualization of in-depth exploration and reconsideration resembles the distinction between exploration in depth and exploration in breadth that was originally suggested by Grotevant (1987) and that has been applied by Luyckx, Goossens, and Soenens (2006) in their dual-cycle model of identity formation.

By including commitment, exploration in depth, and reconsideration in our model, we sought to capture Erikson's (1968) dynamic of *identity versus identity diffusion*. Commitment and in-depth exploration on the one hand, and reconsideration on the other hand, are conceptualized as the two opposing forces within this dynamic: whereas commitment and in-depth exploration imply attempts to develop and maintain a sense of self (i.e., identity coherence or synthesis), reconsideration represents questioning and rethinking this sense of self (identity confusion). To measure this three-dimensional model of identity formation, we developed the Utrecht-Management of Identity Commitments Scale (U-MICS; Crocetti, Rubini, and Meeus, 2008) as an extension of the earlier Utrecht-Groningen Identity Development Scale.

As was the case with Marcia's (1966) original dimensions of exploration and commitment, our three-dimensional model can be used to assign participants to identity status categories. For example, using cluster-analytic procedures in a cross-sectional study among 1952 Dutch early and middle adolescents, Crocetti, Rubini, Luyckx, and Meeus (2008) extracted five statuses from continuous measures of commitment, in-depth exploration, and reconsideration. Four of these statuses very closely resembled Marcia's four statuses. Achievement was represented as a combination of high commitment, high in-depth exploration, and very low reconsideration. Moratorium was represented by a combination of relatively low commitment, moderate in-depth exploration, and relatively high reconsideration; foreclosure as high commitment, relatively low in-depth exploration, and very low reconsideration; and diffusion as very low commitment, very low in-depth exploration, and very low reconsideration. In addition to these four statuses, a fifth status also emerged—a combination of high commitment, high in-depth exploration, and very high reconsideration. Crocetti, Rubini, Luyckx, et al. (2008) labeled this status as *searching moratorium* (SM). Adolescents in this status have strong commitments and explore them intensively, but they are also very active in considering alternative commitments. Crocetti, Rubini, Luyckx, et al. found that SMs were empirically distinguishable from "classical" moratoriums in terms of psychosocial functioning—compared to those in classical moratorium, individuals classified into SM were characterized by lower levels of depression, anxiety, and aggression, as well as by more favorable relationships with parents. These findings underscore the differences between the two moratorium statuses and suggest that SMs seek alternative commitments while already possessing strong commitments, whereas classical moratoriums do so with weak or no current commitments.

Within this context, it is important to note that the foreclosed status, as defined by Crocetti, Rubini, Luyckx, et al. (2008), may carry a different psychological meaning depending on the developmental pathways through which adolescents arrive at this status. As a result, in this study, we differentiate foreclosure into two subtypes—"early closures" and "closures." When adolescents begin in the foreclosed status and remain there over time, they can be considered to be "early closures," given that they have strong commitments that were established early on, have not tried to consider alternative commitments, and have not engaged in in-depth exploration of their present commitments. Adolescents, however, also can move from moratorium to this status of high commitment, low in-depth exploration, and low reconsideration. In this case, they have considered alternative commitments, are not engaged in in-depth exploration of present commitments, and should be labeled simply as "closures." Among adolescents with high commitments and low levels of in-depth exploration and reconsideration, we expected that the longitudinal clustering procedures used in the present study would be able to distinguish between closures and early closures.

The differentiation between closures and early closures is intended to highlight the similar profile, but different developmental roots, of these two subtypes of foreclosure. As a result, when we refer to both types of closure, we use the label early closure/closure (ECC). Separate labels—EC for early closure and C for closure—are used to refer to the distinct statuses.

Taken together the findings reported by Crocetti, Rubini, Luyckx, et al. (2008) suggest that our three-dimensional model yields identity statuses that are conceptually quite similar to those proposed by Marcia. Therefore, as is the case with Marcia's statuses, the statuses found with the three-dimensional model can be ordered on an identity status continuum. Diffusion and achievement represent the least and most mature endpoints of the continuum, respectively, with moratorium, SM, and ECC representing intermediate statuses: D–M–SM–ECC–A. Therefore, the identity status continuum generated by the three-dimensional model offers the potential to study change and stability of identity status.

The Present Study: Aims and Hypotheses

The primary goal of this study was to evaluate the extent to which identity statuses represent stable individual dispositions versus states into and out of which individuals move over time during adolescence. Both assumptions of Waterman's (1982) "developmental hypothesis" were evaluated here. Support for the first assumption would take the form of decreases in diffusion, and increases in achievement, over time. Support for the second assumption would take the form of the progressive transitions that Waterman proposed: D → M, D → F, F → M, and M → A. In the terminology used within our identity model, these transitions would be labeled as D → M, D → ECC, ECC → M, and M → A. Based upon the prior literature, we expected to find support for the first assumption. Literature examining the second assumption is fairly scarce, so we treated this as an exploratory research question. These issues were examined using data from a five-wave study, including an early-to-middle adolescent cohort and a middle-to-late adolescent cohort, thereby covering the ages from 12 to 20.

We also examined gender differences in identity statuses and identity transitions. In a review of identity status studies between 1966 and 1995 Kroger (1997) discussed gender differences in overall, interpersonal, and ideological identity. As is common in the identity status literature, she defined overall identity as ego strength and ego synthesis that individuals derive from commitments in a combination of life domains, and interpersonal and ideological identity as ego strength and synthesis that individuals derive from interpersonal and educational or work or political commitments, respectively. Kroger reported no gender differences in overall identity, but she did find that females were more often in achievement in interpersonal identity than males, and that in high school samples males seemed to move into the direction of achievement later than females (Kroger, 1997, pp. 752 and 754, respectively). Studies conducted since 1995 have replicated these findings with regard to interpersonal identity domains such as friendships (Lewis, 2003) and also have found a higher prevalence of females in achievement, along with a higher number of males in diffusion both in overall identity (Guerra & Braungart-Rieker, 1999) and in ideological identity domains (Schwartz & Montgomery, 2002). This pattern of findings suggests that since the 1960s, gender differences appear more often in interpersonal identity than in overall and ideological identity, and more often in high school samples than in college or university samples. Moreover, the more recent findings suggest that gender differences also may be more likely to appear in overall and ideological identity from the late 1990s on.

In this study, we used a Dutch sample where a majority of participants were in high school, and we used and a measure of overall identity that combines interpersonal and ideological domains. In the Netherlands, females may have stronger educational commitment because they have tended to perform better in school than males since the late 1990s (Statistics Netherlands, 2008b, 2008c). Additionally, Dutch females have been found to have stronger interpersonal commitments than their male counterparts (Meeus & Deković, 1995). Given the age and the nationality of our participants and our use of a combination of interpersonal and ideological domains to tap overall identity, we therefore would expect females, compared to males, to be more strongly represented in achievement and less so in diffusion.

Method

Participants

Data for this study were collected as part of an ongoing research project on COnflict And Management Of RElationships (CONAMORE; see Klimstra, Hale, Raaijmakers, Branje, & Meeus, 2009), with a 1-year interval between each of the five available waves. The longitudinal sample consisted of 1,313 participants divided into an early-to-middle adolescent cohort ($n = 923$; 70.3%), who were 12.4 years of age ($SD = 0.59$) on average at baseline, and a middle-to-late adolescent cohort ($n = 390$; 29.7%) with an average age of 16.7 years ($SD = 0.80$) during the first wave of measurement. Because both age groups were assessed during five measurement waves, a total age range from 12 to 20 years was available. The early-to-middle adolescent cohort consisted of 468 boys (50.7%) and 455 girls (49.3%), and the middle-to-late adolescent cohort consisted of 169 boys (43.3%) and 221 girls (56.7%). In both the younger and older cohorts, the vast majority of adolescents (85.1% and 84.3%, respectively) indicated that they were living with both their parents. The remainder of adolescents lived with their mother (7.9% and 7.2% in the younger and older cohort, respectively) or elsewhere (e.g., with their father, with one biological parent and one stepparent, or with other family members). The composition of the two cohorts did not significantly differ with regard to ethnicity. In the younger cohort, 83.4% identified themselves as Dutch, and 16.6% indicated that they belonged to ethnic minorities (e.g., Surinamese, Antillean, Moroccan, Turkish). In the older cohort, 87.4% of participants were Dutch, and 12.6% were ethnic minorities. In the year when the current study was initiated (2001), 21% of all Dutch early-to-middle adolescents, and 22% of the Dutch middle-to-late adolescents, belonged to ethnic minority groups (Statistics Netherlands, 2008a). Thus, ethnic minorities were slightly underrepresented in our sample. With regard to education, all participants initially were in junior high and high schools. Given the Dutch educational system, most participants switched schools at least once during the study. Specifically, participants in the younger cohort switched from junior high school to high school, whereas most of the participants in the older cohort switched from high school to college or university. Because of the sample recruitment procedure, 100% of our middle-to-late adolescents were in high school or college, whereas national demographic statistics (Statistics Netherlands, 2008a, 2008b, 2008c) reveal that 96% of the Dutch middle-to-late adolescents was in some form of education during the time period covered by the current study (i.e., 2001–2005).

Sample attrition was 1.2% across waves: In Waves 1, 2, 3, 4, and 5, the numbers of participants were 1,313, 1,313, 1,293, 1,292 and 1,275, respectively. Missing values were estimated in SPSS (SPSS Inc., Chicago, IL), using the expectation maximization procedure. Little's missing completely at random test produced a normed χ^2 (χ^2/df) of 1.55, which, according to Bollen (1989), indicates that the data were likely missing at random, and that it is safe to impute missing values.

Procedure

Participating adolescents were recruited from various high schools in the province of Utrecht, Netherlands. Participants and their parents received an invitation letter describing the research project and goals and inviting them to participate. More than 99% of the families who were approached signed the informed consent form. During regular annual assessments, participating adolescents completed questionnaires at school or at home. Confidentiality of responses was guaranteed. Adolescents received €10 (approximately US$13) for each wave in which they provided data.

Measures

Identity was assessed using the U-MICS (Crocetti, Rubini, & Meeus, 2008). The U-MICS consists of 13 five-point Likert-scale items (1 = *completely untrue* to 5 = *completely true*), measuring identity in three dimensions: commitment, in-depth exploration, and reconsideration of commitment. Within the ideological and interpersonal domains, the U-MICS consists of five items measuring commitment, five items measuring in-depth exploration of present commitments, and five items measuring reconsideration of commitment. Sample items for the ideological and interpersonal domain include, respectively, ''My education/best friend makes me feel confident about myself'' (commitment), ''I often think about my education/best friend'' (in-depth exploration), and ''In fact, I'm looking for a different education/a new best friend'' (reconsideration of commitment). Although the U-MICS measures identity in different domains, the instrument can be used to assess overall identity. Crocetti, Rubini, Luyckx, et al. (2008) included both ideological (education) and interpersonal (best friend) domains and demonstrated the internal factorial validity of the three-dimensional model across domains. In this study, Cronbach's alphas for commitment, in-depth exploration and reconsideration of commitment ranged in both cohorts from .91 to .93, .88 to .89, and .84 to .94 across waves, respectively.

Analytic Strategy

To address our research questions, we utilized two applications of the general latent class model: latent class analysis (LCA) and latent transition analysis (LTA). Because we wanted to compare the prevalence of the various identity statuses between the early-to-middle and middle-to-late cohorts, we assumed measurement invariance across cohorts; that is, we restricted the profiles of the five identity classes on the three identity dimensions to be the same across cohorts. LCA is a person-centered analytic strategy that is a confirmatory version of cluster analysis. LCA groups individuals into classes based on empirically distinct patterns of scores on the variables (in this case the three identity dimensions) used to create the classes. LCA of continuous variables is sometimes referred to as latent profile analysis. For simplicity, we use the term LCA here. Like confirmatory factor analysis, LCA generates both measurement and structural parameters (Nylund, Asparouhov, & Muthén, 2007). The continuous scores for each of the identity variables within each class represent the measurement parameters, whereas the structural parameters refer to the class membership probabilities assigned to groups of individuals. Unlike cluster analysis, LCA offers fit statistics and significance tests to determine number of classes, it assigns class membership based on class probabilities, thereby taking uncertainty of membership, or error, into account. LCA has been found to be superior to cluster analysis in several Monte Carlo studies (Reinke, Herman, Petras, & Ialongo, 2008). In this study, we applied LCA to test whether the five hypothesized identity statuses would emerge in each of the five waves of measurement.

Latent transition analysis represents a longitudinal extension of LCA (for a recent overview of LTA, see Kaplan, 2008). LTA calculates patterns of stability and change over time in the form of movement or transitions between classes (identity statuses in this case). Like LCA, LTA models use class-specific parameters (the continuous scores for each of the identity variables within each class) as measurement parameters, and class probabilities as structural parameters to estimate the number of participants in each of the classes. To model change over time, LTA adds a second set of structural parameters, latent transition probabilities, to the latent class model. In a two-wave LTA, for example, transition probabilities refer to the probability of moving into class Y in Wave 2 conditional on having been in class X in Wave 1. These transition probabilities range between 0 and 1. In sum, then, LTA offers two types of structural parameters: (a) varying numbers of participants in class across waves, indicating increase or decrease in class size over time, and (b) transitions of individuals between classes that carry these changes of class size. Therefore, LTA is appropriate for evaluating both assumptions of Waterman's (1982) developmental hypothesis, the hypothesized decrease of diffusion and increase of achievement, and the hypothesized identity transitions that carry this increase or decrease over time.

Latent transition analysis results can be converted into contingency tables summarizing the prevalence of classes (identity statuses) across waves. We use Bayesian model selection using (in)equality constraints between the parameters of interest to evaluate these contingency tables. For a more detailed description of this method, readers are referred to Laudy and Hoijtink (2007). Using constraints may express prior information explicitly. This way we can evaluate the likelihood of certain patterns of increases and decreases in identity status membership. Moreover, expected differences in prevalence of identity statuses between early-to-middle and middle-to-late adolescents and males and females can be evaluated.

The results of the Bayesian model selection are expressed in terms of Bayes factors (BFs), representing the amount of evidence in favor of the model at hand compared to another model, and posterior model probabilities (PMPs), representing the probability that the model at hand is the best among a set of finite models after observing the data. PMPs of a model are computed by dividing its BF by the sum of all BFs.

Results

We present our results in four steps. First we apply cross-sectional LCA to explore the number of classes (identity statuses) within each of the five waves. Second, we select the best fitting five-wave LTA model in a number of successive steps. Because we wanted to compare the prevalence of the various identity statuses between the early-to-middle and middle-to-late cohorts, we assumed measurement invariance across cohorts by restricting the profiles of the five identity classes on the three identity dimensions to be the same across cohorts. Third, we apply Bayesian evaluations of the contingency tables generated by the final LTA model. The Bayesian evaluations are intended to address four research questions: (a) Is there a differential increase and decrease of identity statuses across time? (b) Are there differences in the prevalence of statuses across time between the early-to-middle and middle-to-late adolescents? (c) Likewise, are there differences in the prevalence between and males and females? (d) Is there a differential increase and decrease of identity statuses over time between males and females? Fourth, we globally describe the sequence of identity statuses in five-wave identity status trajectories (e.g., moratorium → moratorium → achievement → achievement → achievement in Waves 1 to 5, respectively).

Cross-Sectional Latent Class Analysis

For each of the five waves, we estimated a set of cross-sectional LCAs on the entire sample, including all three identity dimensions simultaneously. Analyses were performed using Mplus (Muthén & Muthén, 2007). We used four criteria to determine the number of latent classes (Nagin, 2005). First, a solution with k classes should result in improvement of model fit compared to a solution with $k - 1$ classes, indicated by a decrease of the Bayesian information criterion (BIC). Second, adding an additional class should lead to a *significant* increase of fit, as indicated by the bootstrap Lo–Mendel–Rubin likelihood ratio test (BLRT; Nylund et al., 2007). Third, entropy—a standardized measure of classification of individuals into classes, based upon the posterior class probabilities—of the final class solution should be acceptable. Entropy values range from 0 to 1, with values of .70 or higher indicating good classification accuracy (Reinecke, 2006). Fourth, we evaluated the content of the classes in the various solutions. If an additional class in a solution with k classes was found to be a slight variation of a class already found in a solution with $k - 1$ classes, we would choose the most parsimonious solution.

As expected, we found the five-class solution to be superior to the one- to four-class solutions on both fit indices across waves. BIC of the five-class solutions was at least 56.21 lower than that of one-, two-, three-, or four-class solutions and only in Wave 5 did the BLRT indicate that the five-class solution did not fit significantly better than the four-class solution ($p = .14$). Entropy (E) for the five-class solution ranged between .74 and .81, indicating good classification accuracy. Adding a sixth class did not provide additional unique information, given that the sixth class was small ($10 > n > 27$ in each wave) and appeared to represent a variation of one of the other classes. Therefore, we decided to use a five-class model in the LTA's.

Five-Wave Latent Transition Analysis

As part of the LTA, we assumed measurement invariance in the five-class LCA solutions across measurement waves. That is, we restricted the profiles of the five identity classes on the three identity dimensions to be equivalent across five waves. We also restricted the variances of the three identity dimensions to be equivalent across classes across waves. Assuming measurement invariance ensures that the profiles of the classes are the same across waves and allows for a straightforward interpretation of transition probabilities (see Nylund, Muthén, Nishina, Bellmore, & Graham, 2006). Figure 1 displays

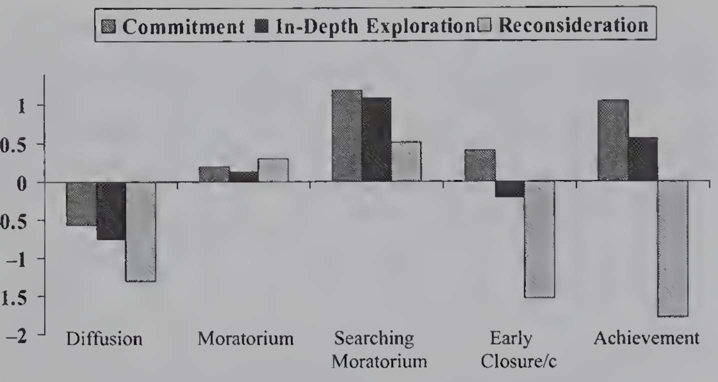

Figure 1. Profiles of the identity statuses on the three identity dimensions across waves.
Note. For reasons of presentation, the scores of the identity dimensions of the statuses were centered at a common scale point (2.75). Early closure/c = early closure/closure.

the profiles of the statuses. Four of the classes (achievement, moratorium, ECC, and diffusion) strongly resemble Marcia's (1966) original statuses. The fifth status, SM, combines very strong commitment with high levels of in-depth exploration and very high levels of reconsideration.

We developed the final LTA model in two steps. We will describe these steps and then present the results of the final model. In both steps, we selected the model with the lowest BIC value. The BLRT is not available for LTA models.

LTA Step 1: Nonstationary versus stationary transition probabilities. In the first modeling step, we compared a model with nonstationary transition probabilities between adjacent waves to a model with stationary transition probabilities. A model with nonstationary transition probabilities assumes that the likelihoods of transitions between classes are different between waves. In contrast, a model with stationary transition probabilities assumes that the probabilities are equal across waves. Results indicated no significant differences in the transition probabilities across time. The BIC for the LTA model with stationary transition probabilities (32,895.71) was lower than BIC of the model with nonstationary transition probabilities (33,112.67). This suggests that adolescents make transitions between identity statuses at the same pace across the four transitions points. As a result, there seems to be a very regular pattern of identity development. Entropy of the stationary model was very good, .85.

LTA Step 2: Are there age and gender differences in identity status transitions? We added covariates to the model with stationary transition probabilities to describe heterogeneity in transitions between statuses. In the first model, we included cohort as covariate to test whether transitions into and out of identity statuses were different between the early-to-middle and middle-to-late adolescents. The second model tested whether transitions were different for males and females. The first model comparison indicated no significant differences in the transition probabilities between the cohorts. The BIC for the LTA without cohort as covariate (32,895.71) was lower than BIC of the model with covariate (32,901.75). The second model comparison indicated significant gender differences in transition probabilities. The BIC for the LTA with gender (32,894.71) was lower than BIC of the model without gender (32,895.71), indicating that the model with gender was 2.72 times more likely than the model without gender (Nagin, 1999). So, rate of change into and out of identity statuses was not different for early-to-middle and middle-to-late adolescents, but was for males and females. Next, we present follow-up Bayesian analyses to clarify the gender differences.

Increase and decrease of identity statuses over time. Table 1 displays the cell sizes for each the five identity statuses for Waves 1, 2, 3, 4, and 5 based on the final LTA model. Findings for the whole sample are in the upper panel of the table. This table indicates a systematic decrease in D, M and SM over time, along with a systematic increase in ECC and A. The table also suggests that ECC is the most prevalent status: Between 50.6% and 55.2% of the sample was classified into that status across waves. A majority of the adolescents had relatively strong commitments along with relatively low levels of in-depth exploration and very low levels of reconsideration. The systematic pattern of increases and decreases in status membership is also found across both cohort and gender (Panels 2 and 3, and 4 and 5 of Table 1, respectively).

We applied Bayesian model selection (Laudy & Hoijtink, 2007) to the upper panel of Table 1 to test which of three alternative models of increase and decrease of identity status best fit the data. Model 1 assumed no increase or decrease of identity statuses across five waves, whereas Model 2 assumed a decrease of D, M, and SM and an increase of ECC and A. In Model 3, the unconstrained model, the distribution of statuses over time was allowed to vary freely. The results are in Table 2. First, Models 1 and 2 were compared to the unconstrained (Model 3). The BFs for Models 1 and 2 imply that after observing the data, these models are approximately 270 and 7,500 times as likely, respectively, as the unconstrained (Model 3). The second comparison revealed that Model 2 is 27.64 times as

5	31	4.6	68	10.1	6	0.9	397	58.7	174	25.7

Note. Findings based on the final stationary 1-year interval model.

likely as Model 1. PMPs of Models 1, 2, and 3 are .03, .97, and < .001, respectively. Note that we assume that before observing the data each model is equally likely. In sum, Model 2, assuming decreases in D, M, and SM and increase in ECC and A, was by far the best fitting model. This model appears to support the first assumption of Waterman's (1982) developmental hypothesis.

Transitions between identity statuses. Transition probabilities of identity status change across 1-year intervals, as found in the final stationary model, are in Table 3. The transition probabilities of identity change between Waves 1 and 5 are displayed on the right-hand side of the table. The 4-year probabilities were calculated using the contingency tables of Waves 1 and 5 as generated by the final LTA model. We added these longer term transition probabilities as a way of elucidating change in identity status across a longer period of time. As expected given the consistency of identity status transition probabilities across time, the transitions during 1-year intervals strongly parallel the transitions during 4-year intervals. Transitions with a relatively high frequency during 1-year intervals were also highly likely during the 4-year interval. Not surprisingly, stability of identity statuses was greater during 1-year intervals than during the 4-year interval, and transitions between identity statuses were more likely to have occurred across 4 years than across 1 year.

Table 2
Bayesian Model Selection: Comparison of Various Sets of Models

	Model comparisons		
Models	BF		PMP
RQ1: Increase and decrease of identity statuses?			
M1. No increase or decrease of D, M, SM, ECC, and A	271.16	1	.03
M2. Decrease of D, M, and SM and increase of ECC and A	7,497.52	27.64	.97
M3. Unconstrained	1[a]		< .001
RQ2: Prevalence of identity statuses different between cohorts?			
M1. No difference in prevalence	0.004	1	< .001
M2. Systematic difference in prevalence	211.50	52,875	.99
M3. Unconstrained	1		< .01
RQ3: Prevalence of identity statuses different between males and females?			
M1. No difference in prevalence	< 0.01	1	< .001
M2. Systematic difference in prevalence	510.73	51,073	.99
M3. Unconstrained	1		< .001
RQ4: More decrease of D, M and SM and increase of ECC and A in males then females?			
M1. No gender-specific increase or decrease	0.004	1	< .001
M2. Gender-specific increase or decrease	5.29	1,322.5	.84
M3. Unconstrained	1		.16

Note. BF = Bayes factor; ECC = early closure/closure; PMP = posterior model probability.
[a]Models with BF = 1 are reference category.

Table 3
Transition Probabilities of Identity Status Change During 1-Year Intervals (n + 1) *and 4-Year Intervals* (n + 4) *Across Five Waves*

	Identity status in year, *n* + 1[a]					Identity status in year, *n* + 4				
Identity status in year, *n*	D	M	SM	ECC	A	D	M	SM	ECC	A
Diffusion (D)	.70	.09	.00	.19	.02	.39	.11	.00	.45	.05
Moratorium (M)	.03	.71	.04	.13	.09	.05	.39	.04	.30	.22
Searching moratorium (SM)	.00	.22	.50	.08	.19	.03	.26	.18	.22	.32
Early closure/closure (ECC)	.02	.03	.00	.90	.05	.03	.06	.00	.80	.11
Achievement (A)	.01	.05	.02	.11	.81	.01	.11	.00	.26	.62

Note. Findings of the final stationary model.
[a]For a stationary model, all transitions probabilities are the same across waves.

Seven specific findings warrant mention here. First, 1-year stability is always more likely than change in identity status. This is also true for 4-year stability of M, ECC, and A, and with two exceptions for the 4-year stability of D and SM, as compared to 4-year identity status change. Notably, 1- and 4-year stability probabilities for ECC and A are very substantial. Second, very few adolescents shifted from M, ECC, and A into D or SM; during 1-year intervals 4% or fewer of the adolescents made this transition, and during the 4-year interval, 5% or fewer did so. Third, transitions into moratorium are limited: during 1-year intervals, 9% of diffusions and 23% of SMs moved into moratorium, whereas during the 4-year interval 11% of diffusions and achievers, and 26% of SMs, moved into moratorium. Fourth, the percentage of transitions into ECC is substantial: between 8% and 19% of the adolescents in D, M, SM, and A moved into ECC during 1 year, and between 22% and 45% did so over the 4 years of the study. The likelihood of moving from D to ECC was very substantial, 19% and 45% during 1 and 4 years, respectively. Given the distinction we have made between early closure and closure in the introduction, the transition out of diffusion should be labeled as D → EC, given that adolescents who make this transition have never reconsidered identity alternatives or explored present commitments in depth. Similarly, remaining in the early closure status should be labeled as EC → EC. However, adolescents who move from SM, M, or A into ECC have considered identity alternatives or have explored present commitments in depth. Therefore, these transitions should be labeled as SM → C, M → C, and A → C. These refer to adolescents who once maintained high levels of in-depth exploration (in the case of regression from achievement to closure) or reconsideration (in the case of movement out of either of the moratorium statuses) and now report low levels of both in-depth exploration and reconsideration. Fifth, few adolescents move from D to A: 2% and 5% during 1 and 4 years, respectively. Sixth, transitions from EC, M, and especially SM into A are quite prevalent: from 5% to 19% and 11% to 32% over 1 and 4 years, respectively. This suggests that the likelihood of a diffused adolescent reaching achievement during adolescence is very low. Seventh, most of the transitions are progressive: from D, M, and SM to the direction of ECC and A. But there are also "regressive" transitions: notably from A to M and C, and from SM to M: 5% and 11%, 11% and 26%, and 22% and 26% during 1 and 4 years, respectively.

In addition, to check whether the stability of the findings is affected by the difference in sample size between cohorts, we estimated a replication of our final stationary model, controlling for sample size differences between cohorts by weighting the cohorts equally in the model. This was done by assigning the weight of 1 to each of the 923 cases of the younger cohort and the weight of 2,366 to each of the 390 cases in the older cohort. The replication confirmed all the earlier reported findings and suggests that they were not affected by difference in sample size between cohorts.

Identity status trajectories. Inspection of the five-wave identity status trajectories revealed two general patterns. First, 822 adolescents were in the same identity status in Waves 1 and 5. The vast majority of the 822 participants (93.7%, or 63% of the total sample) stayed in the same status in all waves. Second, 491 adolescents were in different statuses in Waves 1 and 5: 78.2% of them made only one status transition, 20.4% made two transitions, and 1.4% made three or more transitions during the five waves of the study. So the majority of identity status changers made only one transition. We also found that 11% of the change trajectories were two-transition trajectories in which adolescents passed through SM or M as transitory identity statuses.

These findings partially support the second assumption of Waterman's (1982) developmental hypothesis. We indeed found three of the four progressive identity status trajectories that Waterman hypothesized, notably D → M, D → EC, and M → A. We did not find general support for Waterman's assumption that adolescents starting from diffusion move through more than two identity statuses to reach achievement. We elaborate further on these issues in the discussion.

Age differences. In the second step of LTA modeling, we did not find differences between age groups in rate of change into and out of identity statuses. Table 1, second and third upper panels, summarizes this similar and regular identity change for both cohorts. The table also shows systematic cohort differences in the prevalence of the statuses in Waves 1–5. In all waves, the number of diffusions, moratoriums, and SMs is higher in the younger age group, whereas the number of early closures/closures and achievers is lower. There are a few exceptions to this general pattern: In Waves 3 and 4, the prevalence of moratoriums was lower, and in Waves 4 and 5, the prevalence of early closures/closures was higher in the younger age group. We applied Bayesian model selection to evaluate which of three alternative models of the prevalence of the identity statuses in Waves 1 and 5 in both cohorts provided the best fit to the data. Model 1 assumed no difference in prevalence between the cohorts, whereas Model 2 assumed a higher prevalence of D, M and SM in early-to-middle adolescence and a higher prevalence of ECC and A in middle-to-late adolescence. Model 3, the unconstrained model, did not specify the distribution of statuses across cohorts. Table 2 presents the findings. The BFs imply that Model 1 is 250 times less likely than Model 3, and that Model 2 is 211.50 times more likely than Model 3. Moreover, Model 2 is 52,875 times as likely as Model 1. PMPs of Models 1, 2, and 3 are < .001, .99, and < .01, respectively. Replication of the same Bayesian models for Waves 2, 3, and 4 revealed similar differences between age groups. We do not include a full report of these models to save space. These findings show that the middle-to-late adolescents are generally in more "progressive" identity statuses than the early-to-middle adolescents.

Finally, Table 1 makes clear that the patterns of increases and decreases in identity status memberships unfold quite systematically from early-to-middle and middle-to-late adolescence. Diffusion decreases from 9.3% to 6.6% in early-to-middle adolescence, and from 7.9% to 5.5% in middle-to-late adolescence. For moratorium, the percentages decrease from 17.2 to 14.2 and from 14.4 to 13.3, and for SM the percentages decrease from 7.6 to 2.5 and from 2.1 to 0, whereas the percentages for achievement rise from 16.6 to 21.5 and from 21.8 to 26.2. Percentages for the ECC status rise from 49.3 to 55.3 in the younger cohort but are fairly stable in the older cohort (53.8%–55.1%). So, for diffusion, moratorium, and SM, a systematic decrease is evident from early to late adolescence; for achievement, we observe a systematic increase; and for the ECC identity status, there appears to be an increase followed by stabilization at a relatively high level.

Gender differences. In the second step of LTA modeling, we found gender differences in identity status transitions. Inspection of the separate 1-year transition tables indicated the general pattern of identity transitions to be the same for males and females. The seven primary results that we found for the transitions in the whole sample appeared to generalize across gender. However, one systematic gender difference appeared: In four of the five statuses (M, SM, ECC, and A), 1-year stability was more likely in females than in males—percentage differences were 1, 12, 2, and 4, respectively. To interpret this finding, we estimated two sets of Bayesian models on the two lower panels of Table 1. In the first set, we evaluated gender differences in the prevalence of identity statuses in Waves 1 and 5. Model 1 assumed no difference in prevalence between males and females, whereas Model 2 assumed a higher prevalence of D, M, and SM in males and a higher prevalence of ECC and A in females. Model 3, the unconstrained model, did not specify any distribution of the statuses for either gender. Table 2 presents the findings. The BFs indicated that model 1 is approximately 100 times less likely than Model 3, and that Model 2 is about 510 times more likely than Model 3. Moreover, Model 2 was 51,073 times more likely than Model 1. PMPs of Models 1, 2, and 3 were < .001, .99, and < .001, respectively—and as a result, we retained Model 2. Replication of the same Bayesian models for Waves 2, 3, and 4 revealed the same patterns of differences between males and females. We include no full report of the models to save space. These findings show that females are generally classified into more "progressive" identity statuses than males.

In the second set of Bayesian models, we evaluated three alternative models of gender differences in increases and decreases of identity status membership between Waves 1 and 5. Model 1 assumed no gender differences in likelihood of increase or decrease in the identity statuses over time, whereas Model 2 assumed a larger likelihood of decrease of D, M, and SM in males than in females and a larger likelihood of increase of ECC and A in males than in females. Model 3, the unconstrained model, did not specify any pattern of increase or decrease of identity statuses for either gender. Table 2 presents the findings from these model comparisons. The BFs imply that Model 1 was 250 times less likely to represent the data adequately than Model 3, and that Model 2 was about 5 times more likely than Model 3. Moreover, Model 2 was 1,322.5 times more likely to represent the data than Model 1. PMPs for Models 1, 2, and 3 were < .001, .84, and .16, respectively. These findings show that decreases in D, M, and SM, and increases in ECC and A, are more likely in males than females. Taken together, these findings indicate that females are in more advanced and more stable identity statuses than males, but that males may catch up during later adolescence.

Conclusion. Figure 2 summarizes the main findings of the final LTA model. The figure incorporates only those identity transitions with 4-year probabilities of .10 or above. The figure is based on an additional Bayesian model selection, in which we constrained the probabilities of the 4-year transitions below .10 (see Table 3) to be 0 and the probabilities of the other transition to be greater than 0. This model was clearly superior to a model in which the transitions were allowed to vary freely; PMPs of both models were .99 and .01, respectively. A comparable model comparison of the probabilities of the 1-year transitions replicated these findings. The figure clearly shows that progressive identity transitions outnumber regressive transitions. Identity progression is represented by seven transitions: D → M, D → EC, M → C, M → A, SM → C, SM → A, and EC → A. Identity regression is represented by three transitions: A → M, A → C, and SM → M.

Discussion

Identity Formation: Progression and Stability

This study was designed to test the extent to which identity status is a stable individual disposition or whether it changes over time. Our findings revealed a steady increase of A and ECC, and a steady decrease of D, M, and SM, in both cohorts. These findings support the first assumption of Waterman's (1982) developmental hypothesis and

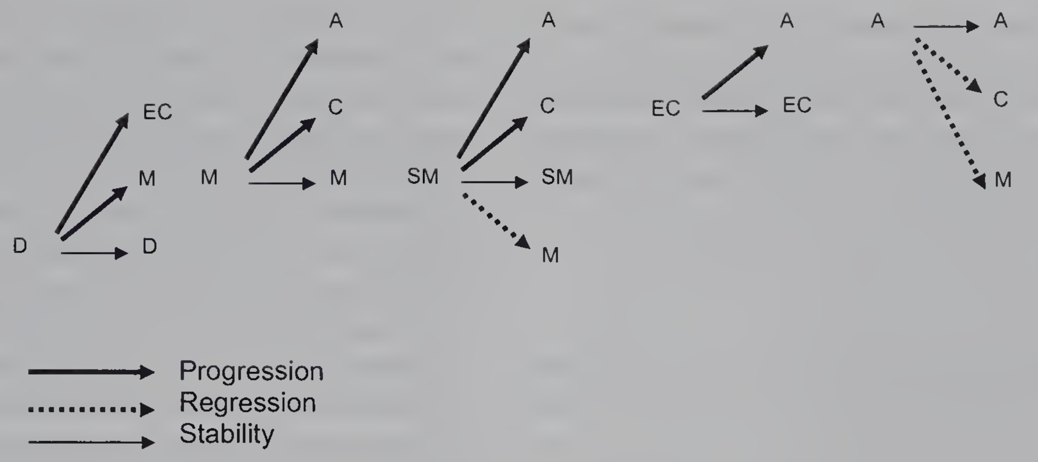

Figure 2. Transitions of identity progression, regression, and stability.
Note. D → EC, D → M, and M → A were hypothesized by Waterman (1982) as progressive transitions, and A → M as regressive transition. Percentages of the number of participants that changed statuses between Waves 1 and 5 can be found in the right-hand side of Table 3 (e.g., .11 signifies that 11% of the participants who were in diffusion in Wave 1 moved to moratorium in Wave 5).

document identity progression: growth of the high-commitment statuses (ECC and A), decrease in the number of adolescents who do not address identity issues (D), and decrease in the proportion of adolescents who are in the process of finding their identity (M and SM). Taken together, these findings clearly demonstrate identity maturation during adolescence, and they converge with the results of Klimstra et al. (2009), who have provided evidence for systematic personality maturation between early and late adolescence. Support for Waterman's second hypothesis was also substantial, but less consistent: we found support for three of the four progressive identity transitions that Waterman hypothesized, notably, D to EC, D to M, and M to A, and for one of the four regressive transitions he proposed: notably A to M. On the other hand, we also found substantial support for the individual difference perspective: Sixty-three percent of the adolescents remained in the same identity status in Waves 1 and 5. This percentage is remarkably similar to the 59% found in the longitudinal identity status studies reviewed in the introduction. So our study replicates earlier findings on change and stability of identity. We offer two interpretations for the high stability of identity status that we found. The first interpretation assumes that changes in identity may be more prevalent in emerging adulthood than in adolescence due to more frequent and intense consideration of adult roles. Some support for this position has been obtained in a recent meta-analysis of personality change by Roberts, Walton, and Viechtbauer (2006), who concluded that personality change is much more prevalent in young adulthood than in adolescence. The second assumption states that the universality of the identity conflict and subsequent identity formation has been wrongly and too commonly assumed. Support for this interpretation has been found in the review by Kroger (2007), who showed across cross-sectional and two-wave longitudinal studies no more than 25% of participants to be in moratorium. Future longitudinal studies from early adolescence into emerging adulthood are needed to more thoroughly test these alternative interpretations.

Another major finding is that Marcia's (1966) original four statuses—achievement, moratorium, foreclosure (here ECC), and diffusion—indeed emerged empirically as identity statuses at all five waves, along with a new status: searching moratorium. Our findings strongly suggest that SM is an early and middle adolescent status that disappears in late adolescence. So, in late adolescence (corresponding to the age group that Marcia used in his own research), we empirically extracted Marcia's four identity statuses. It is also of interest to note that the five-wave LTA model was characterized by high classification accuracy ($E = .85$).

Interestingly, we found the ECC status to be the most prevalent in both cohorts. A majority (80%) of the 725 adolescents who were in this status in Wave 5 can be considered to be early closures: They stayed in this status in all waves ($n = 530$) or made the transition from diffusion to early closure ($n = 53$). They are labeled as early closures because they have not considered identity alternatives and have continued to maintain relatively strong commitments over time. A minority (20%) of the adolescents with an ECC profile transition from moratorium, SM, or achievement. They have considered identity alternatives and therefore cannot be defined as early closures. We have labeled them as closures. At present, they possess relatively strong commitments and maintain them in an automatic way. They did not, however, always do so. We will discuss this issue further in the section on limitations and suggestions for further research.

Identity Transitions

Figure 2 summarizes the main findings of the final LTA model. The transitions depicted in this table are predominantly progressive. Identity progression is represented by seven transitions: D → M, D → EC, M → C, M → A, SM → C, SM → A, and EC → A. Identity regression is represented by three transitions: A → M, A → C, and SM → M. The seven progressive transitions indicate different changes in the identity configurations of adolescents: starting to think about alternative commitments (D → M), making stronger commitments (D → EC), making stronger or much stronger commitments along with decreases in considering alternative commitments (M → C and M → A, respectively), making much more secure (SM → C) or much more secure and active (SM → A) commitments, and making more active and strong commitments (EC → A). The three regressive identity transitions indicate discarding commitments and starting to consider alternative ones (A → M), moving from strong and active commitments to more rigid and less active commitments (A → C), and discarding commitments while maintaining high levels of reconsideration (SM → M).

The analyses of status transitions imply that the high-commitment statuses, A and ECC, are more likely than the other statuses to serve as endpoints of identity formation in adolescence. Stability of A and ECC is very substantial, and recent studies have documented that both statuses show more positive profiles of psychosocial adjustment compared to diffusions or moratoriums. Achievers and adolescents in foreclosure or ECC tend to be characterized by relatively low levels of depression (Meeus, 1996), anxiety (Berman, Weems, & Stickle, 2006), substance use (Luyckx, Goossens, Soenens, Beyers, & Vansteenkiste, 2005), aggression (Crocetti, Rubini, Luyckx, et al., 2008), and relatively high levels of emotional stability and self-esteem (Luyckx et al., 2005). In contrast to achievement and ECC, SM and diffusion appear to be almost exclusively transitional statuses, given that many adolescents move out of these statuses and few (if any) move into them.

The transitional analyses suggested only a limited amount of change. Few participants shifted from diffusion into achievement or from achievement to diffusion (Table 3). Secondly, analyses of the identity trajectories revealed that the majority of adolescents who change identity status across 5 years make only one transition. This makes clear that changes in identity status tend to be decisive, and that there is an extremely low probability of additional identity status transitions.

The analyses of identity transitions and trajectories shed new light on moratorium and reinforce the distinction between moratorium and SM. First, our findings particularly underscore the transitional nature of SM, as adolescents move primarily out of this status. In fact, there were no SMs in the last waves for the middle-to-late adolescent cohort. On the other hand, our analyses showed moderate stability among adolescents in moratorium. This finding suggests that a considerable number of moratoriums might be unable to move out of this unstable identity configuration, and should be considered as "characterological moratoriums," as Côté and Schwartz (2002, p. 584) have suggested. An important implication of Côté and Schwartz's suggestion is that, for characterological moratoriums, back-and-forth movement between moratorium and achievement, as has been found to occur in adulthood for some people (Stephen, Fraser, & Marcia, 1992), is improbable as an identity trajectory in adolescence. However, moratorium and SM may nonetheless function as transitory statuses. When adolescents make more than one identity transition, they tend to pass through moratorium or SM. "Classical" moratorium, however, may also be characterological, whereas SM appears to be exclusively transitory. In addition, our findings show that SM offers a better starting point to reach achievement than does moratorium: 32% versus 22% (4-year transition probabilities), respectively.

As noted earlier, our findings partially support the second assumption of Waterman's (1982) developmental hypothesis. Waterman hypothesized that progressive identity development would occur through the transitions D → EC, D → M, EC → M, and M → A. We found evidence for the progressive transitions D → EC, D → M, and M → A. The explanation for the nonoccurrence of the transition EC → M is that, as noted before, the early closure status functions very often as the final identity status observed in adolescence. Adolescents in this status do not think a lot about their present commitments and are not active in searching for alternative commitments. Therefore, they do not appear likely to give up their commitments and consider adopting alternative life choices. With regard to regressive transitions, we found support for one of the four regressive identity status transitions that Waterman hypothesized: from achievement to moratorium. Achievers are adolescents with the highest level of in-depth exploration. They are very active in processing information about their commitments. This orientation may give rise to loss of present commitments and search for alternative commitments if one's present commitments are deemed unsatisfactory (Luyckx et al., 2006). We did not find support for the three other regressive transitions that Waterman hypothesized: ECC → D, M → D, and A → D. Our findings clearly suggest that it is almost impossible to go back to a state of disinterest in identity work (D) once individuals have held strong commitments (ECC and A) or have been active in considering alternative commitments (M). In sum, consistent with earlier research (Berzonsky & Adams, 1999; Kroger, 2007; Van Hoof, 1999), we found more progression than regression. At the same time, our findings also make clear that regression in identity is something that cannot be ignored.

Gender Differences

We found considerable gender differences in patterns of identity formation. As expected, females were more likely to be achieved, and less likely to be diffused, than males. In addition, we also found that females were more likely to be classified into the ECC status, and less likely to appear in both moratoria, than males. These findings suggest that, at least at present, females may be "further ahead" of males when overall identity is measured as a combination of interpersonal and ideological (especially educational) domains in adolescence and the early part of emerging adulthood. The explanation might be that Dutch females combine their classic stronger interpersonal commitments (Meeus & Deković, 1995) with stronger educational commitments, given that girls at present often outperform boys in school (Statistics Netherlands, 2008b, 2008c). Our findings are consistent with results of recent studies in the United States that have reported gender differences in interpersonal identity (Lewis, 2003), ideological identity (Schwartz & Montgomery, 2002), and overall identity (Guerra & Braungart-Rieker, 1999). We also found, however, that males tend to "catch up" during adolescence. This is consistent with the review by Kroger (1997), and suggests that earlier physical and cognitive maturation in girls may account for some of this pattern. Recent studies have shown that girls reach puberty between 1 and 2 years earlier than boys (Beunen et al., 2000) and that, in early adolescence, girls tend to be up to a full year ahead of boys in several aspects of brain development (Colom & Lynn, 2004; Giedd et al., 1999). Therefore, girls might reach the mature identity statuses earlier than boys, whereas boys catch up during adolescence.

Limitations and Suggestions for Further Research

A number of limitations of this study warrant discussion. The first limitation involves our sole reliance on self-report questionnaires. Although questionnaires are the most appropriate instruments by which to gather information on subjective processes, such as identity development, the biases involved in self-reports may have come into play. Future research could try to overcome these biases by focusing on the micro processes underlying identity development. This could be done by tapping identity on a day-to-day basis.

A second limitation of our study is its descriptive nature. We did not test explanations of identity progression during adolescence—for example, why certain identity transitions have a higher probability than others. Given that identity status transitions in adolescence seem to be quite decisive, future research should try to specify the conditions that predict the timing of these transitions. Longitudinal designs that include a focus on the link between identity transitions and life transitions, that is transitions in the educational and occupational career and in the formation of intimate relationships, may be a fruitful option here.

Although our model is conceptually distinct from Marcia's (1966) model in two respects, the findings of our study are remarkably similar to those of studies using Marcia's paradigm. Notably, we found similar percentages of change and stability of identity statuses, moratorium to be among the least stable statuses over time, and that the high-commitment statuses are associated with the most positive adjustment profile. Notably, different is the very high prevalence of ECC in our study as compared to that of foreclosure in the earlier studies using Marcia's paradigm. Obviously, this finding requires replication and expansion, for instance by including more domains in an overall identity measure, such as dating relationships, work, religion, and politics. It is also important for future research to examine whether the high prevalence of ECC in our study is due to our use of reconsideration instead of Marcia's original measure of exploration in breadth. Adding a measure of exploration in breadth to the U-MICS could clarify this.

Despite these limitations, this study has contributed significantly to our understanding of the process of identity formation over time. It is the first five-wave study of a broad-range sample of early-to-middle and middle-to-late adolescents to show how identity develops between the ages 12–20 and to elucidate which identity transitions are most likely to characterize these changes. The makeup of our sample suggests that our findings may be generalizable to individuals who are in various types of education during adolescence. Findings of our study may be less generalizable to adolescents who enter the labor force very early and to adolescents from ethnic minority groups. We also clearly demonstrated that statuses with a very clear resemblance to those from Marcia's (1966) model emerged in all waves in both early-to-middle and middle-to-late adolescence. It is hoped that these findings inspire more longitudinal research on identity development.

Structure and Strategies in Children's Educational Television: The Roles of Program Type and Learning Strategies in Children's Learning

Deborah L. Linebarger and Jessica Taylor Piotrowski
University of Pennsylvania

Educational TV has been consistently linked to children's learning. In this research, educational TV characteristics were identified, coded, and tested for their influence on children's program-specific comprehension and vocabulary outcomes. Study 1 details a content analysis of TV features including a program's macrostructure (i.e., narrative or expository) and learning strategies embedded in the macrostructure that support learning in print-based contexts. In Study 2, regression analyses were used to predict outcomes involving 71 second and third graders (average age = 7.63 years). Strategies were categorized as organizing, rehearsing, elaborating, or affective in function. Outcomes were uniformly higher for narrative macrostructures. Strategies used in narratives predicted relatively homogenous relations across outcomes, whereas strategies in expositories predicted quite heterogeneous relations across outcomes.

Since the introduction of *Sesame Street* in 1969, producers, educators, and researchers have worked together and in parallel to create and evaluate the impacts of educational TV. When programs are created using entertaining formats guided by developmental theory, researchers document increases on various outcomes including school readiness (e.g., Wright et al., 2001), problem solving (e.g., Crawley, Anderson, Wilder, Williams, & Santomero, 1999), and literacy (e.g., Linebarger, Kosanic, Greenwood, & Doku, 2004). There is growing evidence that embedding content with certain learning strategies supports children's processing of that content. Showing a word that breaks into individual sounds and then reassembles into the word helps early readers acquire phonemic awareness (e.g., *mm*, *aa*, *pp* when blended together forms *map*; Linebarger et al., 2004; Uchikoshi, 2005) while pairing visual referents with verbal labels or using intonational cues to emphasize content helped children learn more (Fisch, 2004).

Learning involves a relatively permanent change in behavior or knowledge. The most straightforward theories of learning from TV are content based and involve the acquisition, encoding, storage, and retrieval of information. These include behavior change (e.g., social cognitive theory; Bandura, 2001) and information-processing theories (capacity model; Fisch, 2004) that, in their broadest forms, predict that knowledge results from cognitively processing televised content. When children can process and comprehend visual and verbal TV symbols, they will be able to organize, store, and relate this information to prior knowledge. Acquired knowledge and behavior are then used to influence a child's actions.

Focusing attention on particular televised stimuli is dependent on an interaction among interest, ability, and characteristics inherent in stimuli. Becoming sufficiently aroused and oriented to a stimulus while blocking out other, irrelevant stimuli (Herrman, Yoder, Gruneberg, & Payne, 2006) is necessary for learning. Children direct maximal attention to stimuli perceived to be moderately novel and of intermediate complexity (Rice, Huston, & Wright, 1982; Roller, 1990). Declining attention occurs when the material is overly familiar and easy to process, or, conversely, too novel and complex. One way to

boost attention and support content retention is to insert learning strategies that support information-processing efforts. There is considerable variability in the degree of instructional support provided by programs, ranging from those that rely heavily on viewers to generate and apply their own strategies to those that use strategies to explicitly structure viewers' processing in an effort to stimulate learning (Smith & Ragan, 2005).

Recently, educational media began creating content to support the development of early literacy skills. The purpose of this study was to evaluate a set of learning strategies hypothesized to support children's literacy abilities in both narrative and expository programs. To operationalize and evaluate these learning strategies, two studies were conducted. In Study 1, various literacy-promoting learning strategies were culled from print and other literacy-related research and then coded for their presence in children's educational TV. All programs used one of two program types or macrostructures: narrative or expository. In Study 2, learning strategies and macrostructures were used to predict program-specific comprehension and vocabulary.

Study 1

A number of learning strategies that support print-based literacy were identified from several sources (National Institute of Child Health and Human Development, 2000; Snow, Burns, & Griffin, 1998). Because research on the effects of TV on young children has established the crucial role that content plays, because programs with well-designed curricula produce stronger academic and social effects (e.g., Anderson, Huston, Schmitt, Linebarger, & Wright, 2001), and because strategies typically work across different media, it was appropriate to identify learning strategies used in other contexts that might also be found in educational TV. Via an iterative process of review and coding, three key sets of strategies were identified: affective strategies (i.e., literacy environment), comprehension strategies, and vocabulary strategies. Each is reviewed next.

Literacy Environment

Programs may explicitly or implicitly create supportive literacy environments by depicting characters who use print or make positive comments about literacy as well as by displaying print onscreen. Making a decision to invest attention and cognitive resources to televised content is dependent on a child's personal interest, the stimuli characteristics, and the interaction between the two. Personal interest develops when the child's perception of the rewards for engaging in the modeled set of behaviors is strong (Schiefele, 1998). According to Bandura's (2001) social cognitive theory, children observe and imitate persons found in their everyday worlds, including characters on TV, particularly when those characters are interesting and personally relevant. Stimuli characteristics also generate interest and attention when they help children believe they could engage in and successfully replicate onscreen behavior or that literacy is valued and respected. When questioned about their competence in learning from TV and print, the competence scores of poor at-risk second graders were rated more highly for learning from TV (Linebarger, 2001). Motivation levels increased when instruction was based on popular TV programs (Szabo & Lamielle-Landy, 1981). Greater motivation results in deeper processing of content (Renninger, 1992) that, for TV, was found to transfer to higher fourth-grade reading achievement (Szabo & Lamielle-Landy, 1981). Two longitudinal studies involving preschoolers also provide support: Watching educational TV as a preschooler predicted better school readiness skills at school entry (Wright et al., 2001) and more leisure book reading, greater academic self-concept, and higher English grade point averages when a teen (Anderson et al., 2001).

Onscreen print should contribute to literacy skills when that print is a natural part of the plot (e.g., characters write notes or grocery lists; Fisch, 2004; Linebarger et al., 2004). Viewers are given opportunities to practice reading onscreen print with visual (e.g., print grows and shrinks) and verbal supports (e.g., intonation cues). Receiving stimuli in multiple modalities strengthens the connections among these stimuli, resulting in efficient encoding and later retrieval (Sadoski & Paivio, 2001). Incorporating print as an extension of character or program events links it to the main theme, making it more meaningful and easier to remember (Fisch, 2004).

Comprehension Strategies

Constructing meaning from content requires prior knowledge about that content and explicit links between that knowledge and new content. Strategies that support comprehension include activation of prior knowledge (via advance organizers or connections to real life) and repetition and review of the content after it has been presented (Michel & Roebers, 2008). Comprehension is also supported when new information is limited (Reinking & Schreiner, 1985) or when readers are directed to make predictions about upcoming content (Taylor, Peterson, Pearson, & Rodriguez, 2002). Using comprehension strategies should help children remember more of an episode as well as learn the underlying educational content in that episode.

Vocabulary Strategies

Children are able to learn specific words from TV as well as transfer that knowledge to more generalized vocabulary gains (Rice & Woodsmall, 1988; Wright et al., 2001); however, these associations hold only for educational TV (e.g., Patterson, 2002). Naigles and Mayeux (2001) concluded that when designed appropriately using strategies that support word learning in print-based contexts, educational TV helps vocabulary acquisition. TV affords a unique opportunity to present words and concepts using a combination of images, verbal description, and sound effects. When supporting text is simple, more challenging content can be inserted. The simple text requires little processing and, as such, directs attention to the central content and away from incidental content. The rate of aural narration also affects what and how much is comprehended. Pairing static text with narration (e.g., books on tape) increased reading vocabulary and definition knowledge when narration rates were similar to or just above the child's reading rate (McMahon, 1983). Televised and audio-taped book narration rates average 141 words per minute (wpm), children's educational TV averages 124 wpm, and cartoons average 125 wpm (Jensema, McCann, & Ramsey, 1996). Conversation rates are between 150 and 175 wpm (Taylor, 1964). While first to third graders are able to comprehend content at these speeds, it begins to decline as speeds reach and surpass 175 wpm (Barron, 2004). Lower rates are required when children have reading difficulties or when content is especially complex (e.g., science content is more challenging than prosocially themed stories at faster narration rates; Barron, 2004). While these studies do not exactly mirror the process of viewing and comprehending TV, recent research finds that similar skills underlie processing of different media. Comprehension of televised stories at age 6 predicted reading comprehension at age 8 (Kendeou et al., 2005).

Program Type: Narrative Versus Expository Macrostructures

In addition to learning strategies, the broader macrostructure used to deliver content affects learning. While different narrative macrostructures exist (e.g., traditional story book, story within a story; Linebarger & Piotrowski, 2009), the foundational elements used in most narratives are similar (e.g., setting, character, goals, resolution). In contrast, expository macrostructures present information in varied ways depending on the purpose of the information (e.g., compare and contrast, listing and sequencing, cause and effect; Duke & Kays, 1998). Embedded within both macrostructures are learning strategies that support processing by reducing cognitive load and making content accessible and salient. It is unclear whether these strategies function similarly across macrostructures or whether their influence is dependent on, shaped by, or interacting with the macrostructure. It is likely that these strategies function in both ways.

The skills used to interpret content and those that develop from repeated exposure to content differ by the macrostructure used. Reading expository books contributes to conceptual knowledge and vocabulary development, stronger comparative and contrastive abilities, and the use of classificatory language structures (Duke & Kays, 1998). In contrast, exposure to narrative stories supports language and literacy skills, story knowledge, and later school success (e.g., Nord, Lennon, Liu, & Chandler, 1999; Scarborough & Dobrich, 1994).

Television programs also use these two macrostructures although little research has specifically focused on the effects of these macrostructures. Narratives contribute to language and literacy skill acquisition (Kendeou et al., 2005; Linebarger & Piotrowski, 2009; Linebarger & Walker, 2005). Watching narratives over an extended period helped preschoolers augment story knowledge and print-based narrative skills compared with children who viewed an expository or no program (Linebarger & Piotrowski, 2009). Story knowledge and narrative abilities develop from the ability to identify the meaning of a particular story. When a program uses a narrative macrostructure, children should be better able to recognize story parts (e.g., goals, characters, setting) and, more important, the deeper educational content (Fisch, 2004).

The utility of expositories, comparisons between these programs and narratives, and comparisons between these programs and comparable expository printed texts, have not been directly evaluated.

There is, however, sufficient evidence that children learn content from expositories and are able to transfer that content to more generalized knowledge gains (e.g., Fisch, 2004). Questions remain about what content is best learned through which macrostructure and whether particular learning strategies support or interfere with learning that content.

Method

Sample

Six 30-min programs previously or currently airing on the Public Broadcasting Service (PBS) channel were selected for inclusion in this study. Curriculum documents and promotional materials developed by each of the programs indicated that these programs were designed for children in the target age group (i.e., 7- to 9-year-olds). PBS programs were selected because (a) PBS is widely available and free, (b) not all children in the study had access to cable (e.g., for programs on Nickelodeon or Disney), and (c) there were no commercials on PBS. In addition to airing on PBS and targeting second- and third-grade children, an equal number of narrative and expository macrostructures were included. Narratives used a set of story events containing dialogue, characters, setting, goals, and outcomes to deliver prosocial or academic content. Expositories used multiple vignettes and program hosts to educate, inform, or describe a particular topic. As the goal of this research was to make more general statements about macrostructures and embedded learning strategies (vs. claims about particular programs), selecting six different programs equally representing both macrostructures provided stronger tests of our hypotheses. *Arthur & Friends* (ART), *Magic School Bus* (MSB), and *Wishbone* (WB) were selected as narrative exemplars. *Reading Rainbow* (RR), *Zoom* (ZM), and *Kratts' Creatures* (KC) were selected as expository exemplars.

Coding Framework

Literacy environment. To evaluate whether the literacy environment depicted in an episode was conducive to learning, the following were coded: character's use of print (i.e., reading books, writing, using the computer; Print Use), character's positive statements about print (i.e., frequency; Positive Statements), and onscreen print (i.e., frequency that print onscreen lasted at least one second; Onscreen Print).

Comprehension strategies. Four comprehension strategies were coded. An episode's number of main segments was counted (i.e., segments introducing new information related to an overall theme; Main Segments). Pre- and postmain segments were coded as Prior Knowledge or Summary, respectively. Prior Knowledge was the duration in seconds that characters or a narrator spent directing viewers to access their own background knowledge. Summary was the duration in seconds when the information in a Main Segment was repeated exactly or paraphrased after its initial presentation. Characters' or narrator's use of questions and predictions related to upcoming content were scored as Questions/Predictions (i.e., frequency).

Vocabulary strategies. A variety of components related to vocabulary were coded including number of times target words repeated (i.e., Target Words), number of words per sentence (i.e., Sentence Length), the percentage of Dolch words used (i.e., Dolch Words; Dolch words represent 220 high-frequency words that comprise 50%–70% of kindergarten through third-grade primers; May, 1998), and the pace or rate of the aural narration (i.e., Narration Rate).

Reliability

Krippendorff's alpha (Hayes & Krippendorff, 2007) was calculated to examine intercoder reliability for frequency counts and durations. Frequency counts were tallied for Print Use, Positive Statements, Onscreen Print, and Questions/Predictions, while durations were computed for Prior Knowledge and Summary. All codes demonstrated strong intercoder reliability: Print Use = .99, Positive Statements = .96, Onscreen Print = .99, Prior Knowledge = .97, Summary = .98, and Questions/Predictions = .99.

The number of Main Segments was identified together with each coder prior to coding the other variables. Vocabulary codes were calculated using Concordance software (Watt, 2007). After entering episode scripts, the software counted the total number and frequency of all words (including Target Words and Dolch Words) and the average words per sentence (i.e., Sentence Length). Narration Rate was calculated by dividing the total words spoken by the episode air-time. Table 1 provides descriptive data, and Table 2 provides correlations among all variables.

Analytical Approach

To facilitate comparisons across codes and programs and balance the contribution of each strategy

to the overall models, all coded variables were *z*-score transformed. Six (programs) by *N* (category of coded variables) repeated measures analyses of variance (ANOVAs) with repeated measures on the categories (e.g., Literacy Environment, $N = 3$: Print Use, Positive Statements, Onscreen Print) were computed to examine code-related program differences. To evaluate whether macrostructures differentiated strategy use, ANOVAs comparing each type were computed. In these analyses, *z* scores were used to generate the *F* tests reported in Table 1. To ease interpretation, the original means are presented in Table 1. Because the sample size was low (i.e., $N = 6$) and to estimate practical significance, effect sizes are also reported in Table 1. All reported results are significant at alpha level $p < .05$ or better.

Results

Variability in Strategies Across Programs

Literacy environment. To test for differences in the depiction of the literacy environment across programs, a 6 × 3 (Programs × Literacy Environment) repeated measures ANOVA with repeated measures on the last factor was conducted. The literacy environment was marginally variable across programs ($p < .10$). RR contained the densest literacy environment followed by ART, ZM, KC, WB, and MSB.

Comprehension strategies. To evaluate whether comprehension strategies differed across programs, a 6 × 4 (Programs × Comprehension Strategies) repeated measures ANOVA with repeated measures on the last factor was computed. Comprehension strategies significantly varied across programs while the distribution and quantity of each was similar within programs. MSB contained the most comprehension strategies followed by WB, KC, ZM, ART, and RR.

Vocabulary strategies. To examine variation in the use of vocabulary strategies, a 6 × 4 (Programs × Vocabulary Strategies) repeated measures ANOVA with repeated measures on the last factor was computed. Vocabulary strategies varied marginally across programs. ZM contained the most, followed by KC, RR, WB, MSB, and ART. The distribution of strategies within programs also differed. The density of all four strategies was higher than average in ZM and lower than average in WB. Both KC and RR contained more strategies than average across three of the four codes (i.e., KC contained a lower than average percentage of Dolch Words while RR contained a slower than average Narration Rate). The reverse was true for ART and MSB; both contained fewer than average strategies for three of the four codes. ART's Narration Rate was faster than average while MSB repeated Target Words more often than average.

Macrostructure Differences

Literacy environment. To test if the literacy environment varied by macrostructure, a 2 × 3 (Macrostructure × Literacy Environment) repeated measures ANOVA with repeated measures on the last factor was computed. The literacy environment did not vary by macrostructure.

Comprehension strategies. The macrostructure was hypothesized to differentiate comprehension strategies such that narratives would use more effective comprehension strategies. This hypothesis was tested by computing a 2 × 4 (Macrostructure × Comprehension Strategies) repeated measures ANOVA with repeated measures on the last factor. This hypothesis was supported. The significant two-way (Macrostructure × Comprehension Strategies) interaction indicated that narratives used more supportive comprehension strategies and fewer comprehension obstacles compared with expositories (i.e., longer Prior Knowledge and Summary segments, more Questions/Predictions, fewer Main Segments than expositories).

Vocabulary strategies. Macrostructure was hypothesized to differentiate the use of vocabulary strategies such that expositories would use more effective vocabulary strategies. To test this hypothesis, a 2 × 4 (Macrostructure × Vocabulary Strategies) repeated measures ANOVA with repeated measures on the last factor was computed. This hypothesis received partial support. The significant two-way (Macrostructure × Vocabulary Strategies) interaction indicated that expositories contained more of all strategies, supportive (i.e., more repetitions of Target Words, greater percentage of Dolch Words) and unsupportive (i.e., longer Sentence Length, faster Narration Rates) when compared with narratives.

Discussion

Study 1 confirmed modest to high levels of variability in learning strategies across and within programs. Macrostructures provided a framework to which microlevel learning strategies were affixed. Significant variability by macrostructure for comprehension and vocabulary strategies was found while the literacy environment was depicted similarly for both.

Narratives contained fewer main segments, easier program text, and more time spent activating prior knowledge and summarizing program content. These strategies should reduce the cognitive resources needed to make sense of content by explicitly instructing viewers to access relevant background knowledge and by offering time to reflect on new content during summaries. Children, by virtue of their considerable narrative experience (e.g., 92% of the top 25 children's programs in 2003 used narratives, Nielsen Media Research, 2003; 90% of books in kindergarten through third grade use narrative formats, Stein & Trabasso, 1982), should be able to devote fewer resources to processing narrative macrostructures, freeing up cognitive capacity to generate inferences.

Conversely, expositories are organized to transmit information and, as a consequence, contained more unique content ideas and greater structural complexity than narratives. As a result, expositories tend to demand greater organizational and processing skills than is typically required for narratives (Best, Floyd, & McNamara, 2008). Both supportive and unsupportive vocabulary learning strategies were highest in expositories while comprehension strategies were used less frequently than narratives. It is unclear whether the supportive vocabulary strategies (i.e., target words, Dolch words) are more powerful than the unsupportive strategies (i.e., longer sentences, faster narration rates), leading to higher literacy scores or whether vocabulary complexity nullifies the supportive vocabulary strategies, leading to lower literacy scores. In contrast, the lack of explicit comprehension supports makes it likely that viewers will encounter difficulty linking their own knowledge (which, for at-risk children, is often limited) to the new information, resulting in diminished program comprehension.

Study 2

Research and theory assert that children's vocabulary knowledge and comprehension abilities will be higher for programs that depict a more positive literacy environment, that use more comprehension strategies, and that use more vocabulary strategies. Understanding program content results from a child's ability to recognize the macrostructure used to present that content as well as the microlevel strategies that define the organization of and elements within a particular media text. The microlevel strategies refer to how ideas are arranged and connected to one another and how visual or verbal cues signal key content. This is successfully accomplished when children are familiar with the purposes behind a particular macrostructure and, more specifically, with the strategies that act as cues for key information. Based on Study 1, it is hypothesized that each macrostructure delivers content using distinct microlevel strategies that are tied to that particular macrostructure type. Narratives use coherent and sequential text structures to present content. In contrast, expositories use text structures that pattern information according to the purpose of the expository text (e.g., sequential, cause and effect, compare and contrast). Because children have little experience with expository texts, it is likely that they will experience difficulty in learning from these programs.

Macrostructures organize content by pairing it with specific learning strategies to convey information. First, the effects of the two macrostructures on children's vocabulary and comprehension scores were evaluated for significant differences. Next, two sets of regressions were used to link strategies to outcomes for each macrostructure independently (i.e., comprehension strategies predicted outcomes for narratives and expositories separately). These analyses were performed to identify which strategies predicted what outcomes. All reported results are significant at alpha level $p < .05$ or better.

Method

Participants

After securing permission from principals at four elementary schools, teachers sent consent forms home with students of the target age. Parents of 71 second- and third-grade children attending four Title 1 public schools in two large Midwestern cities provided consent. Forty-two were girls ($M = 7.5$ years) and 29 were boys ($M = 7.8$ years). This age was recruited because the children had at least 1 year of basic reading instruction, resulting in some ability to decode words, a necessary skill for the original closed caption intervention (Linebarger, Piotrowski, & Greenwood, 2010). Eighty-two percent of the families reported incomes below $30,000, 5 children had an identified reading/learning disability, and 54.3% of the children had oral reading rates below a benchmark indicating risk for reading failure (Good & Kaminski, 2002; second-grade at-risk threshold ≤ 43 wpm, third-grade at-risk threshold ≤ 76 wpm). There were 52.6% at-risk second graders (i.e., at-risk $M = 22.3$ wpm, all other second graders $M = 71.2$ wpm) and 61.5% at-risk third graders (i.e., at-risk $M = 45.3$ wpm, all other third graders $M = 93.6$ wpm). Children were recruited from urban schools in predominantly low-socioeconomic-status (SES) communities: Fifty-six percent were African American children who spoke English as their first language and the remaining 44% were Hispanic children learning English as a second language (i.e., English language learners).

Procedure

After obtaining parental consent, all participating children completed a series of pretest assessments to measure baseline literacy skills. Following pretesting, children viewed one episode per visit across 12 visits. Video stimuli were presented to groups of 2 to 3 children using a 13-in. TV/VCR combination unit positioned approximately 1–2 ft away from them. Experimenters sat to the right and slightly behind the children and were directed to interact very little except to redirect attention to the screen in the event that it became necessary. The viewing took place in empty classrooms during the after school program hours at each of the schools. After viewing each episode, children participated in a short, individually administered posttest (i.e., there were enough research assistants to test all children immediately after viewing).

Measures

Program-specific vocabulary knowledge. Vocabulary knowledge was assessed in two ways: word fluency and definition knowledge. Children read five target words selected from each video after viewing the video. All words from each program were counted, categorized, and selected if they connected to an episode's main themes but were not function words (e.g., articles, prepositions, auxiliary verbs, participles; Watt, 2007). With these criteria, 60% of the words were nouns (e.g., *notch, warrior*), 27% were verbs (e.g., *arrive, locate*), and 13% were adjectives (e.g., *thirsty, rude*). Examiners scored children's word reading for accuracy and fluency (4-point scale: 0 = *inaccurate*, 1 = *read with difficulty*, 2 = *sounded out*, 3 = *fluent*; Word Fluency). Examiners were trained and practiced until interexaminer agreement on fluency scores equaled 90% or higher. After reading each target word, children were then asked to provide a definition. If the child was unable to read the target word, a clear pronunciation was provided prior to asking for the definition. Definitions were scored on a 3-point scale (0 = *no or inaccurate response*, 1 = *partially correct definition*, 2 = *accurate and complete definition*; Definition Knowledge). Two independent raters scored 11% of the definitions. Krippendorff's alpha indicated strong intercoder reliability for all definition scores ($\alpha = .93$).

Program comprehension. Comprehension questions included a literal and an inferential question for each episode. The literal question asked children to identify a critical story event that was visually and verbally presented (e.g., "When X happened what happened next?") while the inferential question required the children to provide the main idea of the program (i.e., "What do you think [program] was trying to teach you?"). Comprehension questions were scored on a 3-point scale (0 = *no/inaccurate response*, 1 = *partially correct answer*, 2 = *accurate/complete answer*). Two independent raters scored 11% of the answers. Krippendorff's alpha was acceptable for both literal comprehension ($\alpha = .91$) and inferential comprehension ($\alpha = .86$).

Baseline vocabulary knowledge and literacy ability. Prior to viewing any videos and after viewing all 12 videos, children read a list of all target words ($n = 60$ words). Although not the focus of this article, children demonstrated significant growth in video-specific word fluency scores from pre- to posttest (i.e., 16.5% growth; Linebarger et al., 2010). General literacy ability was measured using two DIBELS tasks: Nonsense Word Fluency (NWF) and Oral Reading Fluency (ORF; Good & Kaminski, 2002). Mean performance was 52.8 letter-sounds per minute (NWF; $SD = 29.3$) and 48.9 wpm (ORF; $SD = 32.1$).

Analytical Approach

Each validation outcome (i.e., Word Fluency, Definition Knowledge, Literal Comprehension, Inferential Comprehension) was z-score transformed to facilitate comparisons across literacy skills in each relevant analysis. Next, to control for potential third variables associated with the child's baseline literacy ability, a covariate was constructed by z-score transforming scores on the two pretest DIBELS literacy tasks and then summing these variables. Because these analyses were taken from a larger intervention study evaluating the effectiveness of closed captions on the literacy skills of two different populations (i.e., low-SES African American children and English language learners; Linebarger et al., 2010), we included two controls to extract the variance from the relations among strategies and child outcomes: intervention condition (i.e., one group saw all videos with captions while the other saw the same videos without captions) and the child's primary language. In preliminary analyses, the patterns of results were the same for both English- and Spanish-speaking children (i.e., all results were in the same direction; however, the findings were more robust for English language learners); therefore, adopting this strategy (i.e., controlling for primary language) appeared reasonable. Gender was unrelated to any of the outcomes and was dropped from further analyses.

To assess potential dependency issues resulting from viewing all 12 videos, two sets of intraclass correlations were calculated: between-subjects differences across children (i.e., .12–.16) or between-subjects differences across video (.92–.94). Larger intraclass correlations indicate that either videos or children (depending on the analyses performed) are more likely to share a common experience resulting in violation of the independence assumption. Given the larger variation between videos versus between children, dependency associated with individual performance across the 12 videos was minimal (Guo, 2005).

Results and Discussion

Two repeated measures analyses of covariance (ANCOVAs) were computed to examine child outcomes by macrostructure. Table 3 contains means, standard deviations, and ANCOVA results. Although there were no significant differences for literacy environment codes, it was possible that macrostructures would mediate the relations between codes and outcomes; therefore, regressions predicting outcomes using three sets of codes (i.e., literacy environment, comprehension strategies, vocabulary strategies) were conducted separately for each macrostructure. Both unstandardized (*B*) and standardized (β) coefficients from the regression models are found in Table 4. An alpha level of .05 was used for all statistical tests. Only interaction and main effects relevant to the hypotheses are presented next.

The Role of Macrostructure on Comprehension and Vocabulary Knowledge

Program comprehension. Based on Study 1 findings, we hypothesized that comprehension scores would be higher after viewing narratives compared with viewing expositories. To test this hypothesis, a 2 × 2 (Macrostructure × Comprehension Outcomes) repeated measures ANCOVA with repeated measures on the last factor was computed. Our hypothesis was supported. Comprehension was higher for narratives compared with expositories although the effect was qualified by a significant two-way

(Macrostructure × Comprehension Outcomes) interaction. Literal comprehension was higher after viewing narratives while inferential comprehension was higher after viewing expositories. Univariate tests indicated that differences were significant for literal comprehension, $F(1, 847) = 36.70$, $\eta_p^2 = .042$, and marginally significant ($p < .10$) for inferential comprehension, $F(1, 847) = 2.85$, $\eta_p^2 = .003$.

Program-specific vocabulary knowledge. Based on Study 1 findings, we hypothesized that program-specific vocabulary knowledge would be higher after viewing expositories compared with viewing narratives. To test this hypothesis, a 2 × 2 (Macrostructure × Vocabulary Outcomes) repeated measures ANCOVA with repeated measures on the last factor was conducted. Our hypothesis was not supported. Main effects for Vocabulary Outcomes and Macrostructure were significant. Definition knowledge was higher than word fluency while vocabulary knowledge overall was higher after viewing narratives compared with expositories.

As with comprehension, the Macrostructure main effect was qualified by a significant two-way (Macrostructure × Vocabulary Outcomes) interaction. As predicted, word fluency was higher after viewing expositories. Contrary to our prediction, definition knowledge was higher after viewing narratives. Univariate tests indicated that these differences were significant for definition knowledge, $F(1, 847) = 18.52$, $\eta_p^2 = .021$, and not significant for word fluency, $F(1, 847) = 0.98$, $\eta_p^2 = .001$.

What Is the Relation Between the Literacy Environment and Children's Program Comprehension and Program-Specific Vocabulary Knowledge by Macrostructure?

Recall that character's use of and positive comments about print and onscreen print were hypothesized to create a conducive learning environment. For narratives, two of the three codes predicted outcomes. Positive statements about print and onscreen print positively predicted literal comprehension and both vocabulary outcomes while characters' print use supported literal comprehension and suppressed word fluency and definition knowledge.

Unlike narratives, there were no consistent patterns between the literacy environment and outcomes within expositories. Each time characters used print, definition knowledge scores dropped, literal comprehension improved, and inferential comprehension marginally improved. Positive statements about print supported definition knowledge and suppressed word fluency. Onscreen print negatively predicted definition knowledge, word fluency, and inferential comprehension and positively predicted literal comprehension.

What Is the Relation Between Comprehension Strategies and Children's Comprehension and Vocabulary Knowledge by Macrostructure?

There were four comprehension strategies: main segments, time spent directing viewers to access prior knowledge, time spent summarizing a main segment, and total questions/predictions used to highlight upcoming content. Results were fairly consistent for narratives; that is, most coefficients were in the same direction (although some were unrelated) across outcomes. As main segments increased, literal comprehension and both vocabulary scores decreased. Spending time activating prior knowledge predicted higher vocabulary and inferential comprehension while time spent summarizing main content suppressed literal (marginally) and inferential comprehension. As characters' questions and predictions increased, vocabulary performance and literal comprehension increased while inferential comprehension decreased.

For expositories, the results were less consistent. As main segments increased, word fluency and literal comprehension suffered while definition knowledge improved. Activating prior knowledge both positively predicted vocabulary outcomes and negatively predicted literal comprehension. In contrast, longer summaries predicted lower definition knowledge and higher literal comprehension. As the number of questions and predictions increased, definition knowledge and inferential comprehension decreased and literal comprehension increased.

What Is the Relation Between Vocabulary Strategies and Children's Program Comprehension and Program-Specific Vocabulary Knowledge by Macrostructure?

Vocabulary strategies consisted of four coded variables: frequency of target word use, average sentence length, percentage of Dolch words, and the narration rate. Interestingly, for narratives, none of the vocabulary strategies predicted word fluency or definition knowledge. Literal comprehension declined as repetition of target words and the narration rate increased. Inferential comprehension declined as sentence length increased while it improved as the percentage of Dolch words increased.

For expositories, the role of vocabulary strategies was much more prominent. Word fluency scores decreased as the narration rate, the sentence length and the percentage of Dolch words increased. Definition knowledge scores decreased with each repetition of a target word and increased with faster narration rates, longer sentences, and a higher percentage of Dolch words. Literal comprehension increased with each repetition of a target word, and decreased with faster narration rates, longer sentences, and a smaller percentage of Dolch words. Inferential comprehension scores marginally increased with longer sentences.

General Discussion

In Study 1, a set of learning strategies were identified and coded across two episodes of six children's TV programs. Programs were further categorized using one of two macrostructures: narrative or expository. In Study 2, working with a population of children from low-SES homes at risk for literacy difficulties, we evaluated the general effects associated with watching content presented within each macrostructure as well as whether and how the coded strategies embedded in each macrostructure predicted vocabulary and comprehension.

The Role of Narrative and Expository Macrostructures

Study 1 established that narrative macrostructures contained more learning strategies hypothesized to support comprehension outcomes while expository macrostructures contained more of both supportive and unsupportive strategies hypothesized to predict vocabulary outcomes. We further hypothesized that narratives would predict stronger comprehension performance while expositories would predict stronger vocabulary performance. Study 2 partially confirmed these hypotheses. When viewing narrative macrostructures, all outcomes were higher compared with outcomes when viewing expository macrostructures.

Programs using narrative macrostructures tell stories with a beginning, middle, and end; use characters; include plot or conflict; and create a setting. In other words, they present content in a structurally homogenous way using prototypical story parts. Narrative macrostructures should reduce processing demands due to children's considerable narrative experience in real-life, print-based, and TV-based contexts (Fisch, 2004; Linebarger & Piotrowski, 2009). This narrative experience likely translated into both sensitivity to and automaticity with the structures typical of narratives, making children faster and more competent at identifying story events (i.e., literal comprehension), filling in gaps in presented content, and freeing up valuable cognitive resources to make connections to real-life situations or broader themes (i.e., inferential comprehension; Smith & Ragan, 2005). As predicted, identification of literal story events was stronger for narrative macrostructures. Although narratives were expected to make it easier to refocus cognitive resources toward making broader connections, children infrequently did this (Linebarger, 2001). Previously, deep processing was more likely to occur if content was moderately novel and of intermediate complexity while superficial processing occurred with content that was overly familiar or excessively challenging (Rice et al., 1982; Roller, 1990). With experience, processing narratives becomes automatic and children are more likely to allocate minimal resources to them.

Unlike the prototypical format of narratives, programs that use an expository macrostructure present content in structurally heterogeneous ways (Best et al., 2008). Based on Study 1, watching expositories was expected to predict stronger vocabulary outcomes when compared with narratives because expositories used more supportive vocabulary strategies. Contrary to this prediction, vocabulary performance (particularly definition knowledge) was higher after viewing narratives versus expositories. The structural heterogeneity inherent in expositories offers an explanation. When processing unfamiliar content delivered through an expository macrostructure, children must simultaneously process the new content and the general purpose of an expository text to effectively learn the content. Duke and Kays (1998) contend that young children can learn from expository texts but, because they are not consistently exposed to these formats until as late as fourth grade, learning from expository texts is difficult and frustrating.

The Role of Learning Strategies

In Study 1, three categories of learning strategies embedded in children's educational TV were identified and coded: strategies depicting a supportive literacy environment, strategies supporting comprehension, and strategies supporting vocabulary. Despite selecting strategies with evidence of their effectiveness in other contexts, the hypothesized effects were not uniformly present. Instead, relations between strategy and outcome differed by strategy type, program macrostructure, specific child outcome, or some combination of these three factors. Refocusing interpretation to the cognitive activity generated by a strategy clarified the inconsistent findings. Smith and Ragan (2005) proposed five broad types of learning strategies: organizing, rehearsing, elaborating, metacognitive, and affective. The first four strategies elicit specific cognitive activity while affective strategies create environments that trigger attention to and increased engagement with content. No metacognitive strategies were coded in this study.

An additional layer of complexity was introduced by the macrostructures used to deliver content. As described, macrostructures introduce a framework for content through their use of particular and predictable learning strategies that arrange ideas and make connections among these ideas. Narrative macrostructures use a fairly uniform set of strategies and children's accumulated experiences with narratives are substantial. Coupling predictability with experience suggests that narratives may be better macrostructures for delivering content, especially when that content is unfamiliar or complex. Unlike narratives, expository macrostructures are highly variable and dependent on the purpose of a program or the unique characteristics of particular content. Expositories can include strategies that describe a topic, present sequential or chronological information, introduce cause and effect, or highlight similarities and differences. Because young children have little experience with expository forms, learning content embedded with these forms may prove challenging. Recent evidence suggests that introducing expository text in preschool or early elementary school can help children become familiar with a range of expository forms and subsequently mitigate difficulties that arise when children shift from learning to read to reading to learn around fourth grade (Duke & Kays, 1998).

Organizing strategies structured content by encasing it within a common framework and by using simple supporting text to increase attention to conceptual content (Smith & Ragan, 2005). In this study, simple supporting text was defined by more high-frequency words (i.e., Dolch words), longer but less complex sentences (sentence length), and narration rates that did not exceed the average wpm that children this age are able to adequately process (i.e., narration rate; Barron, 2004). These strategies worked in concert to increase or decrease the volume of content contained in an episode. Greater use of main segments was associated with more unique content ideas that structured the presentation and flow of that content. As main segments increased, the narration rate sped up considerably while the sentence length modestly increased. Sentence length was more highly related to Dolch words, suggesting that sentences became longer by using more high-frequency words while narration rates became faster due to more content words. The latter relation indicates cognitive overload.

Narratives with more main segments negatively predicted word fluency, definition knowledge, and literal comprehension likely because extra main segments were indicative of more irrelevant subplots, making it hard to keep the plot points together. Both vocabulary outcomes and literal comprehension suffered as a result. These difficulties were compounded when dialogue was spoken faster and sentence lengths were longer. Simplifying the content came at a cost as definition knowledge suffered. Without key conceptual content or extended discussions about particular concepts, viewers were able to provide limited definitions. Inference generation was supported with shorter dialog segments filled with more high-frequency words.

Expositories contained more main segments, longer sentences, more Dolch words, and faster narration rates. As a result, word fluency and literal comprehension suffered. In contrast, the conceptual understanding needed to provide solid word definitions was supported by more volume. Main segments tended to build on each other throughout an expository episode. The three expositories used in this study contained multiple examples and descriptions that linked to the theme of that episode. For example, in RR, one episode about humpback whales featured multiple vignettes that defined this type of whale from several viewpoints, including a scientist, a whale-watching boat captain, the host, and a nonfiction book.

Rehearsing strategies directly supported the encoding and retrieval of information by providing multiple opportunities for practice. Coded strategies were repetition of target words and repetition of main segment content (i.e., summaries). When content is repeated, it signals that it is important and should be attended to. Repeating target words is a fairly simple rehearsal tool while providing main segment summaries is a more complex rehearsal strategy.

When narratives used more rehearsal strategies, comprehension was better. Children's experience and facility processing narratives freed up resources to devote to comprehending content. By spending time repeating content, children were better able to identify story events (i.e., literal comprehension) and, more important, generate inferences about these events.

Rehearsal strategies embedded in expository macrostructures aided acquisition of definition knowledge and, to a lesser extent, literal comprehension. Expositories contained noticeably more content than narratives. To ensure adequate comprehension of vocabulary, expositories included multiple rehearsal opportunities (i.e., words averaged 27 repeats and summaries averaged 8 min). Interestingly, summaries were almost 2 min longer in narratives, a finding that may explain why outcomes were higher after viewing narratives.

Elaborating strategies help learners create links between new content and existing prior knowledge. Two strategies elicited this cognitive activity: time spent activating viewers' prior knowledge and total questions and predictions made about upcoming content. Both strategies enabled viewers to establish associations between new information and prior knowledge, to identify key concepts or story events, and to increase the personal relevance of the content.

When narratives used more elaboration, all outcomes were higher especially vocabulary. As with the other cognitive strategy types, when used in a narrative macrostructure, children were able to devote their attention to conceptual information and story events rather than needing to split time simultaneously to make sense of the presentation format and the content.

Elaboration strategies used in expositories predicted more definition knowledge and inferential comprehension. Elaborating is a demanding cognitive activity because it requires that children understand program content, possess knowledge about how content links to the macrostructure, and connect content and strategy to relevant background knowledge. Using too many elaborating strategies impeded literal comprehension likely because they directed attention to conceptual understanding and away from key events. In the comprehension hierarchy, knowing story events is less important over time while generating inferences or themes is more important.

Frequently using affective strategies should influence engagement with and motivation toward attending to content resulting in a more favorable learning environment. Three affective strategies were hypothesized to create such an environment: characters using print, characters making positive statements about print, and the display of onscreen print. These strategies were conceptually linked to three instructional conditions found to influence learning: demonstration of the desired behaviors by a respected role model, opportunities for practice using those behaviors, and reinforcement of those behaviors (Gagne, 1985; Smith & Ragan, 2005).

Narratives supported program-specific learning (i.e., word fluency, definition knowledge, literal comprehension) when characters made positive statements about print or text was displayed onscreen. Characters using print hindered literal comprehension and both vocabulary outcomes. The characters using print may not be likeable or credible or there may have been too little explicit reinforcement of the benefits of print (Gagne, 1985; Smith & Ragan, 2005). These explanations are supported by the positive relation between positive statements and outcomes. Onscreen print provided opportunities for reading practice and elaboration by providing visual and aural cues that make print more salient and easier to decode. While the literacy environment helped children learn program-specific content, this learning did not transfer to inferencing.

Connections between affective strategies and outcomes were less consistent for expositories. Modeling print use predicted both comprehension outcomes but impeded definition knowledge while positive statements predicted stronger definition knowledge and impeded word fluency. Onscreen print supported literal comprehension only. The remaining three outcomes were diminished by more onscreen print. These inconsistencies are likely due to a combination of cognitive overload and gaps in knowledge brought on by unfamiliar forms and content.

Conclusion

The results of the two studies indicate that macrostructures and learning strategies must be considered simultaneously to understand how children learn from televised content. To facilitate learning, programs should generate cognitive activity that takes advantage of the broader presentation framework along with particular strategies that lead to learning when used in this framework. Over time and with experience, processing demands shift due to stimulus-specific and person-specific factors. Stimulus-specific factors included macrostructures and learning strategies used to convey content and generate cognitive activity. In contrast, person-specific factors included experience with macrostructures (particularly for expository texts) and accumulated background knowledge about the content and its presentation form. While children typically have more accumulated experiences with narratives, they can, when taught to do so, learn equally well from expository macrostructures. TV provides a unique opportunity to familiarize children with expository structures. There is clear evidence that TV comprehension is linked to reading comprehension; that is, TV comprehension was highly correlated with print comprehension in preschool (Linebarger & Piotrowski, 2009) and predictive of conventional reading success longitudinally (i.e., TV comprehension at 6 years predicted reading comprehension at 8 years; Kendeou et al., 2005). General processing skills used across media share many commonalities. As such, educational TV can play a vital role in preparing at-risk children in low-SES families to read.

Home Media and Children's Achievement and Behavior

Sandra L. Hofferth
University of Maryland

This study provides a national picture of the time American 6- to 12-year-olds spent playing video games, using the computer, and watching TV at home in 1997 and 2003, and the association of early use with their achievement and behavior as adolescents. Girls benefited from computer use more than boys, and Black children benefited more than White children. Greater computer use in middle childhood was associated with increased achievement for White and Black girls, and for Black but not White boys. Increased video game play was associated with an improved ability to solve applied problems for Black girls but lower verbal achievement for all girls. For boys, increased video game play was linked to increased aggressive behavior problems.

Recent reports emphasize the pervasive influence of the media on children's lives (Roberts, Foehr, & Rideout, 2005). In 1950, only about 9% of American families owned a TV set, but by the early 1980s, when the first systematic examinations of children's time began, 98% of American families owned one (Andreasen, 1994). Since then, there has been a dramatic increase in communication technologies available to the public, all of which are subsumed under the term *media*. Although they may not be new to many adults—three fourths of children lived in a home with a computer in 1999—the usage by children of home computers and video games, what are called *new media*, is relatively recent. In 1999, fewer than half (47%) of children 8–18 used a computer during the previous day, rising to 54% by 2004 (Roberts et al., 2005). In 1999, children 8–18 spent only 27 min in an average day using the computer for recreation at home; that had more than doubled to just over 1 hr by 2004. Another major change was in access to the Internet; the proportion of children living in a home with Internet access rose from 47% to 74% between 1999 and 2004 (Roberts et al., 2005).

As a result of the rapid diffusion of new technologies, research on their effects has been slow to catch up. A recent critique of a leading textbook on children and the media pointed to the lack of systematic information over time on children's use of TV, computers, and other media (Sotirovic, 2005). Comparing children's media use over time is difficult because research reports do not use comparable samples of children and often do not break out results for age groups. In addition, they permit overlap in use. Not adjusting media time for simultaneous use leads to exaggerated estimates of total time spent with media, implying a day of more than 24 hr. Most studies fail to include reliable measures of what else children are doing and what trade-offs between activities are made. Finally, few studies focus on middle childhood, an important period in establishing long-term media habits, one in which large changes in media use are occurring, and one in which the family context is critical.

The present research is the first to examine the implications for children of increased exposure to media at home using nationally representative data. It reports changes in the past decade in the utilization of computers, video games, and TV in comparison with other activities among children in middle childhood. Second, it examines how the utilization of new media is tied to other aspects of children's lives. The introduction of new technologies may change children's TV viewing, alter study habits, and change leisure time pursuits and sleep patterns. Using a widely accepted methodology that ensures that total time not exceed 24 hr in a day and that obtains information not only on media but also on other activities, it examines the association of new media time with playing, studying, reading,

sleeping, sports, TV viewing, and outdoor time. Third, this research examines the consequences of new media use at ages 6–12 for children's achievement and behavior in adolescence 6 years later.

Theory and Review of Literature

Theory About the Effects of Media on Children

The introduction of any new form of media technology leads to a debate about its implications, especially if children have access. Critics of computer use by children focus on two concerns. First, computer use per se may not contribute to development because children learn through creative and imaginative play, which require manipulating the physical environment (Cordes & Miller, 2000; Healy, 1998). Second, computers may displace traditional learning-related activities, such as reading, studying, and nonscreen play that are essential for healthy child development (Van Evra, 2004). However, others argue that media may benefit children. Computer literacy has been touted as the primary avenue to success in the 21st century (Attewell, 2001). Learning how to use computers has potential advantages; most adult jobs require at least minimal computer literacy and many jobs require more advanced computer skills. Playing educational games and searching for information on the Internet can improve children's academic and computer skills.

Theory provides several avenues for potential consequences of media exposure. The first pathway is *social or observational learning* (Bandura, 2002). Media can add to development if they provide new information or stimulate children's learning. Children have been found to gain knowledge about the world and to learn directly and indirectly from media about how to solve problems (Fisch, 2004; Van Evra, 2004). Research using brain imaging documents areas of the brain that are activated in viewing TV, areas associated with memory, face and object recognition, attention, intention, perception, and arousal in threat situations (Anderson, Fite, Petrovich, & Hirsch, 2006). Children also learn how to find information and to manipulate media devices, skills that transcend content.

Research has failed to prove a strong link between computer use and child learning. One study found that children with a home computer reported higher grades than those without a home computer (Rocheleau, 1995); however, other studies found no effects of home computer use on achievement (Subrahmanyam, Greenfield, Kraut, & Gross, 2001). There is one exception; drill and practice programs for learning specific skills have been linked to the skills targeted (Coley, Cradler, & Engle, 1997). Unfortunately, there are only a few studies and the outcomes are mostly self-reported. Another major limitation is that the research to date has failed to specify the use of the computer—for playing games, studying, or communication.

Research has shown that educational TV viewing boosts early literacy and reading habits (Anderson, Huston, Schmitt, Linebarger, & Wright, 2001; Fisch & Truglio, 2001). Besides the benefits that have been found for very young children, educational programs have also been shown to have raised motivation to read, increased knowledge of current events, and improved problem-solving skills in math and science among older children (Fisch, 2004). Given the record of learning from educational TV programming and given the highly interactive nature of games, educational computer or video games have the same or greater potential for learning. Game playing has potentially positive effects, such as improved motor skills, spatial skills, iconic skills (the ability to read images), practice in logic, problem solving, visual attention, and active learning, practice, and discovery leading to mastery (Gee, 2003; Van Evra, 2004). Research has corroborated the effectiveness of game playing for improving spatial skills and visual-perceptual skills, such as improving hand–eye coordination (Subrahmanyam & Greenfield, 1994). Although the emphasis has been on visual and spatial skills, children may seek and read online tips for improving their game strategies and skills. Many games require the same skills that are tested in nonverbal IQ tests (Subrahmanyam et al., 2001) plus a high level of involvement and concentration (Lieberman, 2006).

A second theory, *cultivation theory*, argues that media content affects viewers' beliefs about the world and, consequently, alters their behavior (Gerbner, Gross, Morgan, Signorielli, & Shanahan, 2002). For example, exposure to violent media leads to a belief that aggression can resolve problems with no adverse effects. Under this theory, more time exposed to violent games would lead to more aggressive behavior (Anderson et al., 2001). The gender-stereotyped characteristics and behaviors of game characters reinforce traditional notions of male and female roles (Alloway & Gillbert, 1998; Gerbner et al., 2002), which may lead to lower self-esteem among female players (Lee & Peng, 2006).

Although educational, fantasy, and sports games exist, even those with the broadest age rating can contain mild violence. The pervasiveness of violent and aggressive video games suggests that more exposure means more exposure to violence. A meta-analysis of 35 research reports concluded that exposure to violent games increased later aggressive behavior for both boys and girls (Anderson & Bushman, 2001). Violent game play was associated with aggressive thoughts, aggressive affect, and physiological arousal, with suppression of affective areas of the brain responsible for positive emotions (Weber, Ritterfeld, & Mathiak, 2006). Exposure was more harmful for youth who were more aggressive to begin with (Anderson & Bushman, 2001; Van Evra, 2004). If computers are used to play games, the same outcomes are possible.

Use and motivation theory argues that the impact of media depends upon the uses to which media are put, the motivations (learning, entertainment), and the individual abilities and dispositions of the user (Rubin, 2002). Thus, the context and selectivity of media use need to be taken into account. Young children are more susceptible to influence because their attitudes, beliefs, ideas, and knowledge are developing rapidly and they absorb information from every source. They cannot be expected to have the same sophistication of understanding as do older children or adults. Toddlers, for example, have been shown to learn less quickly and consistently from behaviors modeled on a TV screen than those in real life (Schmitt & Anderson, 2002). Computer use shifts with age; younger children play games whereas older children spend more time accessing Web sites and communicating by e-mail and instant messages (Roberts et al., 2005). Similarly, video game play changes with age. Educational games decline and sensorimotor games increase (Wright et al., 2001). Beginning in about fifth grade, the motivation for video game playing is challenge and fantasy. As children age into junior high school, social motivation comes into play, including interaction around games, competition, and sharing of strategies (Van Evra, 2004).

Media use is highly gendered. Although there are few differences in TV viewing or computer use, boys devote more time to video game play than girls. An important aspect of game playing, both video game and computer game play, is the reinforcement of gender-differentiated peer group culture (Sefton-Green, 1998). Games may provide opportunities to compete and cooperate around game playing, thus facilitating social interaction. Male talk often centers on discussions of games and problem solving (Vered, 1998). Because in most games the main character is male and the activities are also male oriented (von Salisch, Oppl, & Kristen, 2006), it should not be surprising that boys develop a greater interest in and expertise in video games and spend more time than girls playing such games (Roberts et al., 2005). Boys prefer more aggressive games whereas girls prefer well-developed characters and stories and bring different expectations and norms to the play setting, eschewing yelling and aggression (Vered, 1998). Because of the different amount and type of video game play by boys and girls, their behaviors may be differentially influenced (Subrahmanyam & Greenfield, 1994). Greater use of educational game play may give girls' achievement a boost (von Salisch et al., 2006). For boys, game playing could lead to involvement in supportive peer groups rather than to isolation. This may be especially the case for video games, which provide multiple controllers, compared with computer games that have only one mouse. For girls, game playing could lead to greater social isolation, especially if they play games on the computer rather than on hand-held consoles. For both genders, greater use of the computer for communications, such as e-mail and instant messaging may lead to greater social involvement.

Research shows African Americans and Hispanics to have greater overall media exposure; however, this is due to the latter's heavier time spent watching TV. Substantial racial/ethnic differences in home computer access have been documented, with African American and Hispanic 2- to 7-year-olds averaging only 60% of the usage of White children of the same age (Roberts, Foehr, Rideout, & Brodie, 1999). Because of their lower access to other learning-related resources, children from minority families may benefit more from having access to a computer at home than children from majority families (Wright et al., 2001). As children enter school, learning resources increase, but most time is still spent at home. Black children are also disadvantaged at school; children living in zip codes with an annual median income below $25,000, more likely to be the residential location of Black and Hispanic families, had about one fourth of the exposure to computers of those with incomes over $40,000 (Roberts et al., 1999). African American boys may not experience the same peer group culture that focuses on video games as do White boys. Because most of the early media research was conducted using White middle-class samples in the Midwest, we have less information about differential effects of media use among different race/ethnic groups. Thus, it is important to investigate whether there are differential effects of computer and video game use across racial/ethnic groups separate from income. That is, the effect of media use on reading and math scores and behavior may vary by race, independent of income and education (Attewell & Battle, 1999).

Parental characteristics and behavior may moderate the effects of media (Nikken & Jansz, 2006) because children are dependent upon them for both media and control over their subsequent behavior. Children whose parents have less education and whose families have lower incomes have been shown to have less access to computers than their more advantaged peers (Attewell, Suazo-Garcia, & Battle, 2003; Roberts et al., 1999; Roberts et al., 2005).

In sum, greater exposure to media facilitates learning the what (content) and how (technical skills) of the information displayed. It also promotes socialization into peer cultures. Media's effects are dependent upon the context in which their use takes place and characteristics of child and family (e.g., age, gender, and race; Fisch, 2004). In addition, whether media are used for game play, study, or for communication may influence outcomes.

Consequences can also occur because media used for entertainment or social activities may displace activities such as studying, reading, physically active sports and outdoor activities, nonscreen play, and sleep, which positively contribute to health and development. Thus, the fourth theory, *displacement theory*, is that media use displaces important developmental activities (Anderson et al., 2001; Neuman, 1995). A negative association is expected; because time is limited, if you do more of one type of activity you have less time for other activities. *Which activities are displaced and by how much is the important issue.* There are at least three possible mechanisms of displacement: First, new media displace functionally equivalent activities (e.g., video games displace computer games); second, new media replace similar but less structured activities (e.g., computer play displaces nonscreen play or outdoor activities); and third, new media displace less satisfying activities or activities with smaller benefits at the margin (e.g., computer games displace studying or sleeping).

One of the major concerns of developmental psychologists is that the use of computers and video games could reduce children's social involvement and increase isolation. The limited research available has been unable to document a negative association of computer use with social behavior, perhaps because some social interactions, such as communication with friends, are facilitated by computers (Subrahmanyam et al., 2001). A recent study that provided home computers and Internet access to families who did not previously have such access found significant short-term (1-year) declines in social involvement but these effects weakened after the 1st year (Subrahmanyam et al., 2001). Research has found that increased computer and video game use altered interaction patterns as families incorporated media into their lives (Mitchell, 1985; Nikken & Jansz, 2006), but there was no overall negative impact. Several studies found greater computer use by children associated with watching less TV (Neuman, 1995; Wright et al., 2001) and another found greater computer use associated with less time in sports and outdoor activities (Attewell et al., 2003).

Small amounts of media use are unlikely to indirectly affect achievement and behavior because they do not displace much other activity time. Thus, a curvilinear effects hypothesis is reasonable. That is, although low to moderate usage could promote positive achievement and behavior through social learning, *heavy usage* could displace time spent studying, reading, playing, and interacting with peers, and this may lead to reduced achievement and increased social isolation, low self-esteem, and inability to relate to others (Lee & Peng, 2006; Subrahmanyam et al., 2001). One study found low (but not high) computer use to be associated with more time spent reading and greater letter–word recognition, reading comprehension, and mathematical calculation achievement test scores among elementary schoolchildren (Attewell et al., 2003). However, another study found heavy computer use to be associated with greater achievement by adolescents (Rocheleau, 1995).

Finally, video game play may displace the typical activities in which children engage, leading to social isolation or overdependence on games. More time in video games is likely to interfere both with more accepted learning-related activities and with physical and social activities, such as sports and informal outdoor activities. One study found video game play leading to less prosocial behavior, such as donating to others (Chambers & Ascione, 1987). Because no prior research has examined the displacement effect and there is little known about its association with achievement, more systematic research is needed.

Are Media Effects Causal?

Does media use reduce participation in other activities, does having fewer other activities lead to increased media use, or does something else both reduce other activities and increase media use? Children and their parents choose how to spend their time. TV and other media serve as entertainment, a way for families to spend time together, and as a source of educational, social, and cultural information (Dempsey, 2005; Jordan, 2004). Outside forces may influence families to take up new media and associated lifestyles and result in changes in children's reading, studying, and leisure activity patterns. Any association between media patterns and reading, studying, and socializing of children may be spurious. Therefore, it is important to control for factors that may influence both media use and children's other activities, including socioeconomic status (SES), maternal education and reading ability, race/ethnicity, number of parents, maternal employment, and number of children. Unlike other behaviors, displacement effects cannot be examined over time because normal development-related activities change as children move into adolescence. At one point in time, some kinds of activities are associated and others are not for individual children, controlling for confounding variables. Negatively associated activities are incompatible; positively associated activities or those with no association are compatible.

Because media use is selective, it is also important to control for initial levels of achievement and behavior in examining outcomes over time. If aggressive children attend to more violent media than less aggressive children; media use may have no additional impact. Additionally, parents who fear negative effects may intervene in advance, thus limiting potential harm (Nikken & Jansz, 2006). A more rigorous test of causality is whether a *change* in media use over time is associated with *change* in behavior or achievement for that same child.

Hypotheses

Displacement of healthy activities. The first hypothesis explored here, from displacement theory, is that the more time spent on media, the less time spent in all other activities considered to be valuable for children's health and well-being, including reading for pleasure, studying, nonscreen playing, sleeping, and playing sports or spending time outdoors. If media displace functional equivalents, then new media should displace old (TV), computer studying should displace noncomputer studying, and video or computer game play should displace each other. If structured displace less structured activities, then computer or video game play would displace outdoor activities, reading, nonscreen play, and sleep. If pleasure is the issue, then computer or video game play would replace noncomputer studying.

Observational learning. The second hypothesis is that computer use will facilitate learning such that children who use a home computer for studying, sending e-mail or text messages, or exploring the Internet will demonstrate higher vocabulary, reading, and problem-solving test scores. Similarly, greater video or computer game play will be associated with improved test scores, particularly on problem solving. However, the benefits of computer game and video game play are likely to accrue at low or moderate levels rather than at higher levels. Greater TV use is expected to be associated with higher achievement if it promotes learning but lower achievement if it displaces studying and reading. Prediction is weak because this study is unable to distinguish educational from entertainment viewing.

Cultivation theory: Behavior problems. The third hypothesis is that greater computer game and video game play will be associated with more behavior problems such as social withdrawal. High video game play will also be associated with more aggressive behavior problems because of its violent content. Finally, greater computer use for communications such as e-mail, instant messaging, and Internet use will be associated with fewer behavior problems because of its positive social networking function.

Use and motivation theory. The fourth hypothesis is that the effects of computer and video game use on achievement and behavior will differ by the race/ethnicity, age, and gender of the child. For example, Black children's achievement is expected to benefit from computer use more than that of their White peers. Younger children may be more influenced by computers and games than older children. Finally, because of their greater selection of violent games and greater salience to their peer group, boys' behavior may be more strongly linked to their computer and video game use, whereas girls' achievement may be influenced more by variation in computer and video game use because of their lower average usage.

Method

Data

The study sample consisted of 6- to 12-year-old children living with their mothers. The data were drawn from the Panel Study of Income Dynamics (PSID), a 30-year longitudinal survey of a representative sample of U.S. men, women, children, and their families. In 1997 the PSID added a refresher sample of immigrants to the United States. Also in 1997, with funding from the National Institute of Child Health and Human Development, data were collected on up to two randomly selected 0- to 12-year-old children of PSID respondents both from the primary caregivers and from the children themselves, the Child Development Supplement (CDS). The first CDS survey period began in March 1997 and ended in early December 1997 with a break from mid-June through August; thus, the study took place only during the spring and fall. Interviews were completed with 3,563 children in 2,380 child households with a response rate of 88%. From fall 2002 through spring 2003, the participants in the 1997 CDS were recontacted and another supplement administered. The total potential number of children eligible in 2002–2003 was 3,191, of whom 2,907 (91%) participated in the second CDS. When weights are used, the PSID is representative of U.S. individuals and their families (Fitzgerald, Gottschalk, & Moffitt, 1998).

For the descriptive analysis of activities and for the displacement analysis, the sample used in the present study consisted of 1,951 boys and girls between 6 and 12 years of age in 1997, of whom 1,871 lived with their mothers, and 1,607 boys and girls who were aged 6–12 in 2003, of whom 1,581 were living with their mothers. The 1997 and 2003 CDSs collected complete time diaries for one weekday and one weekend day for 1,448 (77%) of the 1,871 children aged 6–12 in 1997 and 1,317 (83%) of the 1,581 children aged 6–12 in 2003 living with their mothers. Comparisons between children who provided a diary and those who did not showed no significant differences on demographic characteristics.

For the outcome analysis, a longitudinal sample of children 6–12 years of age in 1997 who were reinterviewed in 2003 when they were between 12 and 18 years of age was created. Of the 1,448 children interviewed in 1997 and eligible, 1,226 were reinterviewed in 2003.

Measures

Time Use

The time diary, which was interviewer administered either to the parent or to the parent and child, asked about the child's flow of activities over a 24-hr period beginning at midnight of the randomly designated day. The questions asked the primary activity that was going on at that time, when it began and ended, and whether any other activity was taking place. The full instrument can be seen at http://psidonline.isr.umich.edu/CDS/TDqnaires.html. Activities need to occur regularly to be reliably reported in a diary. The activities selected occur daily (sleeping, nonscreen play, watching TV) or several times per week (studying, reading, video game playing, computer use, outdoor activities, and sports).

Professionally trained staff employed by the data collection organization coded the data to a level of reliability exceeding 90%. Because of extensive follow-up and editing, diaries were complete. Time spent traveling for the purpose of engaging in a specific activity was included in that category but 2 children who were traveling throughout their 2 diary days were excluded. Secondary activities were not included in the analysis presented here. This ensured that time added to 24 hr, making estimates of children's activities exhaustive, mutually exclusive, and additive. Almost no secondary computer or video game use was reported. The same analyses were run using total TV use, primary plus secondary. The results and implications were the same as reported for primary time.

For comparison across time, the primary activities of children were classified into the 18 major categories used by Timmer et al. (1985) in the early 1980s and by Hofferth and Sandberg (2001a, 2001b). Computer time was separated from its original categories such as play, study, and hobbies. Because it could be educational or recreational, computer use was further divided into three categories: playing games, studying, and computer communications. The latter includes activities such as Internet searching, accessing Web sites, e-mailing, and instant messaging. Electronic video game time (such as on Game Boy and other hand-held video game devices) was also separated from the larger *play* category; the remaining noncomputer, nonvideo game play is referred to here as *nonscreen play*. This analysis focuses upon 10 common activities among children: watching TV, nonscreen play, playing video games, playing on the computer, studying using the computer, computer communications, noncomputer studying, reading for pleasure, playing sports, informal outdoor activities, and sleeping. Time spent attending school was used to adjust for the potential amount of nonschool leisure time available to a child. Specific codes used to define each of these categories in

1997 and 2003 are available from the author. The total time children spend in an activity is a function of the proportion who engage in the activity and the time participants spend in it. An estimate of weekly time was computed by summing weekday time (including those who do not participate and have zero time) multiplied by 5 and weekend day time multiplied by 2.

As an alternative measure of time in a media activity, time spent on the computer and playing video games was divided into four categories: no use, low use (under the 25th percentile), moderate use (25th to under the 75th percentile among users), and high use (75th percentile and up). To illustrate, the 25th percentile for computer users was 1.6 hr and for video game users it was 2 hr. The 75th percentile for computer users was 6 hr and for video game users it was 7.2 hr. The results for low and moderate use were similar so they were combined. Because everyone watched TV, viewing hours were divided into low (lowest quartile: under 6.7 hr), moderate (25th–75th percentile: 6.75 to under 18.8 hr per week), and high (75th percentile and up: 18.8 hr plus).

Children's Behavior and Achievement

Children's *socioemotional adjustment* was measured by the Behavior Problems Index, a parent-reported measure of the incidence and severity of child behavior problems using 30 items originally drawn from the Achenbach scale (Peterson & Zill, 1986). This same scale has been used in the Child–Mother study of the 1979 National Longitudinal Survey of Youth since 1986 (Rogers, Parcel, & Menaghan, 1991). Using factor analysis with oblique rotation to permit interfactor correlation, two sets of factor scores, one with 16 items measuring withdrawn or distressed behavior (fearful, anxious, sad, withdrawn), called "internalizing," and one with 14 items measuring aggressive and impulsive behavior (disobedient, argumentative, moody, destructive), called "externalizing," were created. The correlation between these two factors was .51. For our longitudinal sample of 1,226 children whose families were interviewed in both 1997 and in 2003, the alphas were .88 for externalizing and .86 for internalizing each year. The alpha for the total behavior problems scale was .92. After deleting 152 cases missing data on controls, 1,074 boys and girls were included in the behavior problems analysis.

Three subtests of the Woodcock–Johnson Revised Test of Basic Achievement measured *cognitive achievement*: letter–word identification, a test of children's ability to identify and respond to letters and words; passage comprehension, a test that measures reading comprehension skills; and applied problems, a test of skill in analyzing and solving practical numerical problems (Woodcock & Mather, 1989). These were administered in the child's home in 1997 and 2003 by trained interviewers using materials prepared and distributed by the publisher of the test. Mothers were also administered the passage comprehension test. Children had to have a test score in both years to be included. Scores were calculated based on national norms that were age-standardized with a mean of 100 and a standard deviation of 15. Not all eligible children were assessed; therefore, sample sizes were smaller for achievement than for behavior problems. A significantly higher proportion of the children who were not assessed were White because most of such families were in the Midwest, far from population centers where interviewing teams were located. Children who were not assessed were also slightly less likely to live with two parents. Race and number of parents were controlled in the analysis. There were no significant differences on other variables, including media use and other activities. The results suggest that the exclusion of these children from the analysis of achievement did not bias the representativeness of the sample. The sample size was 880 for passage comprehension, 901 for the letter–word test, and 898 for applied problems.

Control Variables

Besides the overall analyses by gender, age, and race/ethnicity, this study examined media use controlling for key demographic characteristics of the family: maternal education (no college, some college, college degree), total family income or the ratio of family income to the poverty line, maternal employment (employed vs. not employed), family structure (1 vs. 2 parents), and family size (1 or 2 vs. 3 or more children). Controls included season of interview (fall = September through November, winter = December through February, spring = March through June) and warm versus not warm state. All the definitions were consistent across the two waves of data except that of maternal employment. In 1997, maternal employment was defined as ever employed in the previous year, whereas in 2003, maternal employment was defined as employed at the time of the survey. The core PSID wave that collected employment information was conducted in 2001 and not in 2002; employment at the survey date was deemed to be a better indicator than employment more than a year prior to the survey. Although included in the displacement analysis, because it had substantial missing data and was never related to any of the child outcomes in the preliminary analyses, maternal employment was dropped in the longitudinal analyses of child achievement and behavior. The difference analysis included a set of dummy variables for whether a change in family structure had occurred (one parent in both years, one parent in 1997 and two in 2003, two parents in 1997 and one in 2003, and two parents both years—the comparison group).

Analysis Plan

Displacement Analysis Using Pooled Sample of Children 6–12

For the displacement analysis, the sample of children 6–12 in 1997 was pooled with the sample 6–12 in 2003, a total of 2,765 children. After deleting 203 cases missing on either date of interview or on maternal employment, there were 1,323 children 6–12 in 1997 and 1,239 children 6–12 in 2003, a total of 2,562 children in the pooled multivariate analysis. All analyses were weighted using population weights provided by the PSID–CDS adjusting for the original probability of selection and for attrition, which were then normalized on the sample. Robust standard errors were computed using Stata to adjust for clustering of children within families and across years. A dummy variable was included to control for the data collection year.

Instead of dividing time into categories (Attewell et al., 2003) or using ordinary least squares regression (OLS; Vandewater, Bickham, & Lee, 2006), the analyses of amount of time spent in the activity were based upon Tobit regression models. These models adjust for the fact that not all children engage in each activity (Tobin, 1958), but they permit keeping time at the interval level. If OLS were used, the regression slope would be biased by the inclusion of zero values. The Tobit coefficients reflect both the effect of the independent variable on the probability of the activity and on the hours spent in the activity by participants (McDonald & Moffitt, 1980). The higher the proportion of children who participate in the activity, the more the results reflect the hours among participants and thus the more similar the results become to those from OLS regressions just on participants. Therefore, for activities in which all or almost all children participate (sleep, play, TV), OLS was used.

Child Achievement and Behavior in the Longitudinal Sample

We conducted two types of longitudinal analyses on a subsample of children who were 6–12 in 1997 and who were interviewed 5–6 years later. Because initial analyses showed significant interactions between media use and gender, all analyses are shown by gender. The first analysis is a lagged dependent variable analysis in which the achievement or behavior outcome of boys (or girls) in 2003 was regressed on media use in 1997, controlling for the same achievement or behavior measure in 1997 and a set of other control variables using OLS. These analyses control, in addition, for the mother's passage comprehension score because previous research has shown that children's scores are linked to maternal reading and vocabulary ability (Shonkoff & Phillips, 2000). The results can be interpreted as the change between 1997 and 2003 in the test score of a child who reported 1 more weekly hour of computer use, video game play, or TV viewing in 1997 compared with a comparable child who reported 1 fewer hour. Interactions between Black race/ethnicity and computer play, computer communications, or video game time are included to test whether such media use differentially affects children of minority racial/ethnic groups. There were too few cases to interact Black with computer study or Hispanic with any of the media variables. Because the ratio of family income to needs was not related to behavior and was related only to the letter–word score of boys (in the unexpected direction), interactions between income and computer or video game use were not examined. An examination of the interaction between age group (6–8, 9–12) and media use showed a consistent interaction between age group and computer study because few 6- to 8-year-olds used the computer for studying. This was not a substantively important finding, and age interactions were not pursued further. The second model examines whether the effects of computer, video game, and TV time are nonlinear, differing for moderate and high users, compared with low users or nonusers.

Our second analysis is a difference analysis. In this more rigorous test, the outcome is the change in achievement or behavior of the individual child across time associated with a change in media time.

Differences in achievement and behavior problems scores were regressed on the difference in hours spent on the computer, playing video games, and watching TV between 1997 and 2003 (2003 minus 1997). Because variables that do not change over time are not included, the only control variables included are age, number of children, household income, and family structure (in dummy categories). The results can be interpreted as the change in child achievement or behavior test score associated with spending an additional hour of time on the computer, video game, or TV between 1997 and 2003, net of the controls. Results are presented separately for White boys, Black boys, White girls, and Black girls. Sample sizes were too small for separate analyses of Hispanic children. Effect sizes (*d*) were calculated by dividing the coefficient by the standard deviation of the dependent variable (Cohen, 1988).

Results

Univariate and Bivariate Findings

Sample Characteristics

To examine time spent in activities in 1997 and 2003, the pooled cross-sectional sample of 2,562 children was used. Of the children in this sample, 41% were 6–8 and 59% were 9–12 (not shown). The sample was evenly split by gender. Three fourths lived with two parents, 44% of the mothers had completed at least some college, and two thirds were employed. Seventy-two percent were White, with 15% Black and 13% Hispanic. The average ratio of income to poverty was 3.4. Most children lived in nonwarm states; only one third of children lived in a warm state. Twenty-seven percent of the interviews were conducted in the fall, 41% in the spring, and 32% in the winter.

Bivariate Analyses of Children's Activities in 1997 and 2003

Columns 1 and 4 of the upper panel of Table 1 show the percentage of all children 6–12 who engaged in each of the media activities (watching TV, using the computer, and playing video games) and other activities (nonscreen playing, sleeping, reading, nonscreen studying, playing sports, engaging in outdoor activities, and spending time in school) in the interview week in 1997 and 2003. Columns 1 and 4 of the lower panel show the average weekly hours spent in each activity each year, including those who spent no time in the activity. Comparable estimates for boys and girls by year are shown in columns 2, 3 and 5, 6. *T* tests were conducted to examine change across time among all children (column 7), change across time by gender (columns 8 and 9), and gender differences within each year (columns 10 and 11).

Overall media activities. In 1997 and 2003 almost all children watched TV (94.8% to 96.6%; Table 1, upper panel). Between 1997 and 2003 the viewing time of 6- to 12-year-olds increased from 13.09 to almost 14 (13.96) hr per week (Table 1, lower panel). The proportion of children 6–12 years old who used the computer in the study week increased from 18.2% to 29.2%. In 2003, children 6–12 averaged about 1.33 weekly hours on the computer, including those who did not spend any time on it.

Screen game play. Computers were primarily used for playing games, a use that increased over the period. The proportion of 6- to 12-year-olds playing games on the computer rose from 14.1% in 1997 to 21.0% in 2003 and the average time (including zeroes) spent playing games increased from 0.58 to 0.81 hr per week. In 2003, younger children were as likely as older children to play games on a computer, 21.9% of 6- to 8-year-olds and 20.3% of 9- to 12-year-olds (not shown). The proportion of children 6–12 playing video games also increased between 1997 and 2003. In 2003, 36.1% of 6- to 12-year-olds played video games, compared with 29.6% in 1997. In 2003, they spent about 2.29 hr a week doing so, compared with 1.52 hr in 1997. The proportion playing video games in 2003 was slightly higher for 9- to 12-year-olds than for 6- to 8-year-old children (39.3% vs. 31.7%, not shown). Gender differences in video game play, in contrast, were large. In 1997, boys were more than twice as likely to play video games (40.7%) as girls (18.5%). In 2003, the proportion of boys playing video games was 56.9% compared with 16.5% of girls and the only significant gender difference in media time was the time spent playing video games. Girls spent 0.82 hr and boys spent 3.86 hr playing video games in 2003.

Nonscreen play. Three fourths of children (73.9%) engaged in nonscreen play. In 2003, the total weekly time 6- to 12-year-olds spent in nonscreen play was 6.33 hr (Table 1, lower panel), representing a 20% decline from 7.85 hr in 1997. Because time spent in computer and video game play increased, total play time (sum of nonscreen, computer, and video game play) declined only slightly,

from 9.95 to 9.43 hr (not shown in table). The fraction of total play time that was represented by computer and video game play increased over the period relative to nonscreen time, from 21% to 33%.

Communications. Although still small, the use of the computer for communications, particularly the Internet and e-mail, more than doubled between 1997 and 2003, from 4.7% to 10.8%. The time spent in such activities rose from 0.14 hr in 1997 to 0.43 hr. In 2003, girls were more likely than were boys to use the computer for communications activities, such as e-mail and surfing the Internet: 12.8% versus 8.7%, respectively.

Studying and reading. The proportion of children who reported spending time studying increased significantly between 1997 and 2003. The increased studying documented here did not result from increased use of the computer for homework. Sixty-six percent of 6- to 12-year-old children reported nonscreen study time in 2003, compared with 58.2% in 1997, an increase of 14%. The total weekly time spent in nonscreen study increased from 2.91 hr to 3.57 hr for all 6- to 12-year-olds. The proportion studying with the computer (2% to 3% of children aged 6–12) and the amount of time spent studying on the computer (0.09–0.10 hr) did not change over the period and both were low.

Increases occurred in reading over the period. In 2003, 47.2% of 6- to 12-year-olds reported reading for fun during the survey week compared with 38.3% in 1997, an increase of 24% over the period. There was also a 31% increase in reading time for the entire age group—from 1.19 to 1.56. Thus, there has been a real increase in reading, though, overall, the proportion and the amount of time spent reading for pleasure were low.

Physical activities and sleep. Sports include formal team sports and informal sports activities for recreation. Outdoor activities include activities such as walking, pleasure drives, horseback riding, gardening, and camping. Participation in sports was lower in 2003 (60.4%) than in 1997 (76.2%). The amount of time spent playing sports was also lower by almost 2 hr in 2003 (3.95) compared with 1997 (5.84). Participation in outdoors activities declined by more than 50% from 1997 (16.2%) to 2003 (10%), and the amount of time spent in such activities also declined over the period, from 0.63 to 0.44 hr. All children sleep, but they may sleep for different amounts of time. The results indicate that time spent sleeping increased slightly from 1997 to 2003 for 6- to 12-year-olds from 69.03 to 70.74 hr per week.

Trade-Off Between Media and Other Activities

The descriptive results show gross change in activities over time; however, they do not adjust for potential differences in family socioeconomic circumstances and seasonality across the 2 years. The bottom panel of Table 2 shows the trade-offs between children's video game time, TV viewing time, and computer time (in the rows) and the key dependent variables of time in nonscreen play, sleep, reading, nonscreen study, sports, and outdoor activities in columns across the top, adjusting for SES and other differences (shown in top panel). The table also includes TV viewing, video game play, computer play, computer study, and computer communications across the top to test cross-media trade-offs. Hours spent in school are controlled to adjust for the hours they have available. Results for boys and girls were similar and are not presented separately.

Is Greater Media Use Associated with Less Time in Unstructured Activities Such as Nonscreen Play and Sleep?

More time on the computer (playing, studying, or communicating), playing video games, or watching TV were all associated with reduced time spent in nonscreen play. The results also showed that greater amounts of time spent playing computer games, using the computer for communicating, and watching TV were associated with less sleep. Neither computer studying nor video game playing was associated with reduced sleep.

Is Reading for Pleasure Displaced by Media?

The more time spent playing video games and watching TV, the less time spent reading for pleasure. However, spending more time in computer play, studying, or communicating was not associated with reduced time reading. In fact, the more hours spent using the computer for studying, the *greater* the time spent reading.

Is Studying Being Displaced by Media?

As with reading, the results showed that greater video game and TV time were associated with less nonscreen study time. The amounts of time spent studying with or communicating using the computer were not associated with time spent in nonscreen studying. However, more time spent playing computer games was associated with less nonscreen study time.

Does Media Time Interfere with Playing Sports or Spending Time Outdoors?

The associations between TV viewing hours and sports time and between computer play and sports time were negative. Video game time, computer study hours, and computer communications were not related to time playing sports. Greater video game time was associated with less time spent in *outdoor activities*, but computer time was not.

Are There Trade-Offs Among the Different Forms of Media?

Video game play and TV time do not appear to be incompatible. Children who spent more time playing video games did not appear to spend less time watching TV; however, there was a negative association between computer studying and TV viewing. Finally, video game time was negatively associated with computer game play and computer communication hours.

Media and Achievement, Lagged Analysis

Table 3 provides the means and standard deviations for the longitudinal file of children 6–12 in 1997 who were reinterviewed in 2003. Black children lived with mothers with less education and a lower vocabulary score, their family was more likely to be headed by a single mother, and their family incomes were lower than those of White children. Black children had lower achievement test

scores than did White children but a similar level of behavior problems. Finally, Black boys and girls were less likely to use the computer at home during the study week but were more likely to watch a lot of TV than were White boys and girls.

Effects of Background Factors on Achievement in 2003

Table 2 showed that, compared with those whose mother had not attended any college, children whose mothers had completed college played fewer video games, watched less TV, and spent more time reading. Similarly, those living in families with a higher ratio of income to needs watched less TV and played more on the computer. These SES–activity links would likely produce a positive association between computer use and achievement and a negative association between video game use and achievement if SES were not controlled.

Main Effects of Study Time on Achievement in 2003

Initial analyses showed significant zero-order associations between computer and video game time and children's test scores, However, when background factors and the child's and mother's 1997 score on that same test were controlled, there were no associations between computer game play hours, computer communications, video game hours, or TV viewing hours in 1997 and achievement in 2003 for boys or girls (Table 4). Two associations were significant. For girls (Table 4, Model 1), greater computer study hours were associated with a significantly lower score on the applied problems test, opposite that expected ($b = -2.31, p < .05$). The effect size (d) was −.14 ($p < .05$) for girls' and −.02 (*ns*) for boys' computer study. Pooling over boys and girls (not shown), the interaction between gender and time spent studying on the computer was significant. Girls who spent more time studying had a significantly lower applied problems test score than boys who spent more time studying. There was also a significant negative association between studying and boys' scores on the passage comprehension test ($b = -0.71, p < .05$). However, this did not differ by gender. The coefficient for girls was about the same size as for boys but was not significant.

Main Effects and Interactions Between Race and Time Spent in Computer Communication

Although the main effects of computer communications and play were not significant, there were substantial main effects of race/ethnicity, with minorities achieving lower scores on all the achievement measures. Black boys, scored 7.77 points lower than White boys, and Black girls scored 3.57 points lower than those of White girls on the passage comprehension test. Interactions between Black race and computer use and Black race and video game use were included in Model 1 of Table 4. The main effects of computer study hours did not change and computer communication and computer play hours were still not significantly associated with the child's passage comprehension score, but the interaction between Black and computer communication hours was significant for several achievement tests. Black boys and girls who spent more time in 1997 in communications activities, such as surfing the Net and e-mail, had passage comprehension scores in 2003 higher by 8.98 and 8.33 points, respectively, than Whites who were similarly active. After adding together the main and interaction effects of Black race and communication to obtain total effects, Black boys' passage comprehension scores were 1.03 points above those of White boys ($d = .06$), and Black girls' passage comprehension scores exceeded those of comparable White girls by 5.92 ($d = .40$), if they used the computer for communication. Black girls also had higher scores than White girls on the letter–word test if they were more active users of computers for communication; the sum of the main and interaction effects was 1.12 ($d = .05$).

Amount of Use

Discrete categorical effects may not be captured by these continuous measures. Less than one fifth of elementary-school-age children used the computer at home during the week in 1997 but the top quartile spent 6 or more hr on the computer. The analysis of media use grouped by low to moderate and high versus no hours (or medium and high vs. low TV hours) is shown in Model 2 of Table 4. *Low to moderate computer hours* were positively and significantly associated with higher passage comprehension scores ($b = 4.12, p < .05, d = .27$) and with marginally higher applied problems scores ($b = 3.21, p < .10, d = .18$), but only for girls. *High video game hours* were, for girls, associated with a significantly lower score ($b = -11.04, p < .05, d = .73$) on the letter–word test and a marginally lower score ($b = -7.75. p < .10, d = .48$) on the applied problems test. There were no associations between the measures of boys' overall computer and video game time in 1997 and their achievements in 2003.

Media and Behavior Problems, Lagged Analysis

Main Effects of Media and Media–Gender Interactions on Behavior Problems

We report results only for total behavior problems; similar results were obtained for internal and external problems. No direct associations between media use and behavior problems were found for boys (Table 4, Model 1). For girls, greater computer play hours were associated with marginally reduced behavior problems ($b = -0.50$, $p < .10$, $d = .05$). There was a significant interaction between gender and computer play. Girls who spent more time playing computer games had a lower behavior problems score than boys (not shown).

Interaction Between Media Time and Race

Media time and race did not interact in their association with behavior problems.

Amount of Media Use

Finally, in Model 2 of Table 4, which categorized media by level of use, spending a greater amount of time on the computer was associated with lower behavior problems for girls ($b = -8.86$, $p < .001$) but not boys, and the effect size was large ($d = .95$). Video game hours were not significantly linked to behavior problems for girls and none of these categories was linked to boys' behavior problems. Moderate TV viewing was associated with greater behavior problems for girls ($b = 7.98$, $p < .05$) but not boys.

Changes in Children's Test Scores, 1993–2003

Table 5 shows the results of regressing the difference between children's 1997 and 2003 achievement test and behavior problems scores on the difference

between children's 1997 and 2003 media time. A positive association means that an increase in media time was associated with an increased score on that particular test. Because the previous analyses suggested differences both by gender and race, the table shows the results separately for White and Black boys and White and Black girls. The same background controls—age of child, number of children, household income, and number of parents—were included in each analysis, but are not shown. A table of effect sizes is available from the author.

Boys' Achievement

Among boys, the relation between computer use and achievement varied by race/ethnicity. For White boys, increased *computer communications* was associated with a significantly lowered score on both the passage comprehension ($b = -0.27$, $p < .05$) and applied problems ($b = -0.28$, $p < .05$) tests. For Black boys, in contrast, increased *computer communications* was associated with increased passage comprehension ($b = 0.95$, $p < .05$). For Black boys, in addition, increased *computer study time* was associated with an *increased* score on the passage comprehension test ($b = 3.71$, $p < .01$). Change in video game time was not associated with change in boys' achievement for any group. Finally, increased TV viewing hours were associated with an increased score on the letter–word test for White boys.

Girls' Achievement

Computer time was consistently positively associated with White girls' achievement. Greater time spent *playing games on the computer* was associated with increased passage comprehension ($b = 0.99$, $p < .05$) and applied problems test scores ($b = 0.98$, $p < .05$) between 1997 and 2003 for White girls.

In contrast to the positive association between computer game play and achievement, *playing video games* was detrimental to the achievement of White girls. For them, increased video game time was associated with a significantly reduced score on the letter–word test between 1997 and 2003 ($b = -0.69$, $p < .05$). For Black girls, increased video game hours were associated with a reduced score on the passage comprehension test ($b = -1.22$, $p < .05$) but with an increased score on the applied problems test ($b = 0.54$, $p < .05$). Increased TV viewing was also associated with a reduced passage comprehension score for Black girls.

Boys' Behavior Problems

For boys, there was no association between computer hours and behavior problems. In contrast, increased time spent playing video games between 1997 and 2003 was associated with increased externalizing behavior problems ($b = 0.01$, $p < .05$). Although the positive relation was found for both Black and White boys, the effect sizes were small, .01.

Girls' Behavior Problems

For White girls, playing more on the computer between 1997 and 2003 was associated with reduced internalizing problems whereas increased time spent studying was associated with increased internalizing behavior problems. Watching more TV was associated with fewer externalizing problems for Black girls. Finally, in contrast to boys, Black and White girls who played more video games between 1997 and 2003 did not experience increased internalizing or externalizing behavior problems.

Discussion

The research reported here described the use of media at home by U.S. 6- to 12-year-olds and linked it to their achievement and behavior in adolescence in 2003.

Change Over Time

Television remains the dominant medium in middle childhood. In 2003, children spent 14 hr per week watching TV, an increase from 13 hr in 1997. The use of computers and video games at home also increased between 1997 and 2003, but the proportion using them and the time spent were still relatively low. Almost 2 of 10 children 6–12 used the computer at home in an average week in 2003, and the average time spent was about 1 hr and 20 min over all children. Three fifths of children's computer time was spent playing games, one third was spent in communications, and the remainder was spent studying. Between 1997 and 2003 increases occurred both in computer game playing and in computer communications, primarily e-mail and Internet use. The small amount of time spent studying did not change. Although total computer time in 2003 was similar for boys and girls, girls were more likely to use the computer for communications and boys were more likely to use it to play games. Video game play was highly gender differentiated. In 2003, 57% of boys and only 17% of girls played a video game during the week of the interview. Including everyone, boys played for almost 4 hr compared with less than 1 hr for girls. This equals 6.8 hr for boys who played and 4.8 for girls who played. Because nonscreen play time declined for all children and computer and video game play increased, screen play occupied a larger fraction of children's total play time in 2003 than in 1997, 33% versus 21%.

Media Displacement of Other Activities

Some displacement was expected. As hypothesized, trade-offs across activities that are functionally equivalent, less structured, and less beneficial at the margin were supported. One example of the displacement of functionally similar activities was that greater video game play time was associated with less computer play time. There was no association between computer and noncomputer study time, indicating that computer studying is not equivalent to and does not displace nonscreen studying. Greater time in any media activity was associated with less time spent in nonscreen play, supporting the hypothesis of substitution of structured for less structured time. Greater use of all media except video games was associated with less sleep, supporting the marginal benefits hypothesis. Although TV time was also expected to decline, greater computer studying was the only activity associated with less TV viewing. The results are consistent with expansion in programming and inconsistent with a negative effect on old media of new media. TV has a unique niche—one that is not easily displaced.

Of new media, only video game play was associated with spending less time in three achievement- or health-related activities—reading, studying, and spending time out of doors. Computer play was also associated with less time spent in sports whereas video game play was not. The availability of sports games may make video gaming attractive to both sports participants and nonparticipants. Playing computer games was similar to playing video games in that each had a negative association with nonscreen studying.

Media Use and Achievement

Computer Use

Consistent with observational learning theory, greater *computer use* overall, particularly low to moderate computer use, appeared to be consistently and positively linked to reading and problem-solving achievement in adolescence 5 years later for girls but not boys. Use and motivation theory was important to the interpretation of the findings because the association depended on whether the computer was used for playing games, for studying, or for computer communications such as e-mail and Internet use. As suggested by use and motivation theory, associations varied by race/ethnicity as well as gender. For White girls, increased time spent playing games on the computer between 1997 and 2003 was associated with an increased score on the passage comprehension and applied problems tests in the change analyses. In the lagged regressions, Black girls who spent more time in computer communications had scores on the passage comprehension and letter–word tests high enough to outweigh their overall lower score compared with White girls. The overall positive effect of computer use for girls reflected the fact that the majority of computer time was spent playing games. This study, unfortunately, had no information on the types of games children were playing on the computer. However, girls of this age are likely to be playing educational games, in contrast to older children who may be playing games of strategy and adventure (Wright et al., 2001). Research indicates that girls are much less facile and comfortable with computers than boys (Vered, 1998); greater experience with them is likely to give girls an achievement edge.

For White boys the results were surprising. There were no positive associations of computer use with achievement in the lagged or difference models for White boys, and there was one negative association: An increase in time spent in computer communications between 1997 and 2003 was associated with a decline in passage comprehension and applied problems scores. Boys may become too involved in the e-mail and Internet functions of computers to focus on their homework assignments. Computers are not a magic bullet to improve children's academic success. Other research suggests that the use of computers for academic work is underdeveloped (Rathbun, West, & Hausken, 2003).

For Black boys, in contrast, the news was somewhat better. As for Black girls, in both the lagged variable and difference analyses, Black boys who spent more time in computer communications and studying between 1997 and 2003 had increased passage comprehension test scores. The results suggest that greater computer use is associated with higher achievement of White girls, Black girls, and Black boys.

Although a significant negative association between computer study and later achievement was found in the lagged dependent variable regressions for both boys and girls, this finding reversed direction in the difference analyses. The difference models found that increased computer studying was associated with an increased score on the applied problems test for White girls and on the passage comprehension test for Black boys. Study behavior is selective; students who are having problems in school may be encouraged to spend more time studying. The difference analysis examined changes in the achievement of the individual student associated with changes in media use across time, eliminating this selectivity.

Video Game Play

In contrast to what was expected based upon observational learning theory, video game playing had neither positive nor negative associations with any measures of boy's academic achievement. However, it had both positive and negative associations with girls' achievement. Even though fewer girls than boys played games, increased video game hours between 1997 and 2003 were associated with a lower letter–word test score for White girls and a lower passage comprehension score for Black girls. At the same time, increased video game hours were associated with an increased score on the applied problems test for Black girls. Video games do not generally improve practice in vocabulary or reading skills; however, they do teach problem-solving skills; the applied problems test is the one test on which Black girls improved their scores with increased video game play. The results support the argument that video game play has the potential to improve learning. However, excessive video game time appears detrimental to learning; a high level of video game play was linked to a reduced applied problems test score for girls in the lagged models. The reason for detrimental effects on learning is that video game time displaces valuable reading and study time. If reading and study time were not displaced, video games could improve learning. Lowered reading and studying time may be more detrimental to girls' reading achievement than that of boys. More research needs to consider the types and circumstances in which girls play video games and to examine differences between the game play of White and Black children.

Media Use and Behavior Problems

Cultivation theory focused upon the types of messages children receive from media. According to cultivation theory, greater computer and video game use should be associated with more externalizing behavior problems because of aggressive content and with more internalizing behavior problems because these are individual activities. Media may also be linked to behavior problems because of displacement of normal outdoor activities.

Computer Use

Consistent across both longitudinal analyses, increased computer game playing was associated with *reduced* internalizing behavior problems for girls, possibly because of social networking. However, consistent with the previous discussion about greater studying linked to school problems, the difference analysis found increased studying linked to *increased* internalizing problems for Black girls. Studying may have social costs in terms of isolation. Computer use did not influence boys' internalizing or externalizing behavior problems.

Video Game Play

Although computer time did not displace outdoor activities, video game play did. The hypothesis from cultivation theory predicting that greater video game use would be associated with behavior problems was supported for externalizing behavior for boys. In the difference analysis, increased video game hours between 1997 and 2003 were associated with increased externalizing behavior problems for all boys but not for girls. Boys who spend more time playing video games spend less time in active outdoor pursuits, which may be a source of these behavior problems. This finding supports other research that has found video game play to be associated with aggressive behavior; however, the effect sizes are quite small in this national sample of children. The results did not support the hypothesis that increased game play would lead to social isolation.

Variation in Media Influence by Race

Use and motivation theory led us to expect that there would be substantial variation in the association between media and children's achievement and behavior depending upon current use levels, motivation, and disposition of the user. Perhaps because of their lower initial level of computer use, the potential of home computer use for achievement was greater for Black boys and Black girls than White boys. Greater time spent with the computer for study and communications was associated with higher achievement for Black boys and Black girls compared with White boys. The boost resulting from computer communications alone was sufficient to offset the substantial Black–White test score gap. Black boys and White boys have a similar risk of increased aggressive behavior problems, but the risk is small. For African American children, the computer provides an opportunity for higher achievement with a minimal risk of internalizing or externalizing behavior problems.

Strengths and Limitations

There were several limitations of the present study. It examined only primary and not secondary media use. Cell phone and music media use, which are likely to fall in the multitasking category, have become widespread, requiring a method for examining how children spend their time that includes multiple uses of time. However, supplementary analyses indicated that incorporating multitasking would not have changed the findings. In addition, this study focused only on computer use at home and did not incorporate computer use in the school setting. Finally, although computer use was divided by type of use, TV viewing content was not examined. This limits the conclusions that can be drawn about the association of TV viewing with achievement. Consistent with this limitation, few associations between TV viewing time and children's achievement and behavior were found and the effects were small. The content of video games was also not considered; the potential association between violent video game time and behavior problems could not be examined.

This study has offsetting strengths. For the first time, this study provides a nationally representative picture of the primary media activities of children 6–12 in 1997 and 2003 in the United States, a description of the changes in media use that occurred in a period of rapid social change, and estimates of the association of changes in media use with changes in children's achievement from interviewer-administered standardized tests and behavior reported by parents.

Implications

This research shows that whereas TV and video games may crowd out positive activities, computer use does not. Home computer use among girls in middle childhood has potential benefits for their achievement in adolescence. The achievement of Black children is associated with greater computer use more than that of White children and there are relatively few risks to behavior for Black children. This research suggests that the vocabulary and reading test score gap between Black and White boys and girls may be at least partially offset through children's higher use of computers at home. Computer literacy is essential for full participation in the information society, and increased access to computers would reduce the disadvantage across generation. Although access and use at school could reduce this divide, most research suggests that, even today, only a fraction of children use computers regularly at school. At present, home computer use is limited among children from minority families; efforts to expand the presence of computers in low-income homes could improve their children's academic performance. The results showing greater potential benefits to Black children also suggest an area in which outreach could help narrow the achievement gap between Black and White children. Benefits also are likely to accrue to Hispanic children; the sample was too small for reliable estimates.

Finally, the conclusions regarding the positive associations of computer game play with achievement do not apply to video game play. Even though boys spend more time playing video games than girls, their achievement does not appear to be significantly affected, at least at the levels of play occurring in 1997 and 2003. Although girls' vocabulary and reading declined with greater video game use, increased video game play was associated with increased problem-solving skills for girls. As expected, moderate use appeared to be beneficial whereas extensive video game time was not. Boys' *behavior* is at risk as a result of video game use; the results showed a consistent detrimental association of video game time with the externalizing behavior of boys, though the effect was small. Greater video game time has been shown in other studies to lead to more aggressive behavior. This is an important caveat for those who write about the potential benefits of electronic game playing. More research is needed to include school use, to incorporate other media and multitasking, and to examine the longer term correlates of media involvement into young adulthood.

The authors tested susceptibility to contagious yawning in 120 children, 1–6 years, to identify the time course of its emergence during development. Results indicated a substantial increase in the frequency of contagious yawning at 4 years. In a second study, the authors examined contagious yawning in 28 children with autism spectrum disorders (ASD), 6–15 years. Children with ASD showed diminished susceptibility to contagious yawning compared with 2 control groups matched for mental and chronological age, respectively. In addition, children diagnosed with Pervasive Developmental Disorder, Not Otherwise Specified (PDD-NOS) a milder variant of autism, were more susceptible to contagious yawning than were children diagnosed with full Autistic Disorder. The authors explore the implications of these findings for theories about the development of mimicry and emotional contagion.

Contagion refers to the tendency of a particular behavior to spread through a group in a "chain reaction." The behaviors that most often trigger contagious reactions in others are those that signify the inner states of others (Hatfield, Caccioppo, & Rapson, 1994). For example, infants in hospital nurseries begin to cry when they hear other babies crying (Hoffman, 1978; Simner, 1971), and laugh tracks accompany most television situational comedies because hearing the laughter of others prompts our own laughter (Bush, Barr, McHugo, & Lanzetta, 1989; Provine, 2000). Similarly, seeing another person yawn, thinking about yawning, reading the word *yawn*, or even hearing the word can elicit a yawn in 40%–60% of normal adults when exposed to such stimuli under experimental conditions (Baenninger & Greco, 1991; Platek, Critton, Myers, & Gallup, 2003; Provine, 1989). Such forms of behavioral contagion may reflect or facilitate *emotional contagion*, which refers to the tendency of individuals to converge emotionally with those around us. The property of contagion, as applied to emotions, offers psychologists an opportunity to study the roots of automatic social behaviors that potentially lay the foundations for the development of empathy.

At least one mechanism by which emotional contagion comes about is via the underlying processes of *mimicry* and *afferent feedback* (Hatfield et al., 1994). Whereas imitation involves the conscious, effortful reproduction of another's behavior, mimicry refers to nonvolitional "matching" behavior (Want & Harris, 2002). As we interact with someone, we often subconsciously mimic (often at a level undetectable to the naked eye or ear) their facial expressions, bodily postures, and speech patterns (see Niedenthal, Barsalou, Ric, & Krauth-Gruber, 2005, for a review).

When a person mimics, the activation of his or her emotional body schemas also creates an emotional reaction that corresponds to the movements being mimicked (i.e., the act of smiling causes us to feel happier). This was first known as *facial* feedback (Capella, 1993), but research has now documented similar effects for gesture, posture, and vocal prosody (see McIntosh, 1996, for a review), and so may be more accurately referred to as *afferent feedback* (Hatfield et al., 1994). The coupling of our automatic tendency to mimic others and the effects of afferent feedback on our own emotional

states may explain the ubiquity of emotional contagion: Because we unconsciously match the emotional movements of others, we unconsciously feel the emotions of others as we interact with them. Similarly, this account of mimicry may explain its psychological utility: Emotional contagion may allow human beings to intuit the feelings of those around us when we interact socially (Rogers & Williams, 2006).

Yawning is a type of mimicry in that it is a matching behavior that is produced unconsciously. The robust effects for contagious yawning found by Provine et al. (1986) when they exposed participants to videos of people yawning disappeared when the participants knew they were being watched (Provine, 2005), supporting the idea that contagious yawning is an unconscious process that may actually be suppressed by conscious awareness. However, contagious yawning appears to be a special kind of mimicry. Unlike the miniscule muscular movements, often undetectable to the naked eye, that mimicry typically entails, yawns—large, obvious sequences of movements, difficult to stop once initiated and lasting for up to 10 s—are a very visible result of such mimicry. The explanation for this may derive from the fact that yawning is a *fixed action pattern* (Provine, 1986). A fixed action pattern is a species-typical behavioral sequence that is indivisible and, once initiated, runs to completion. Fixed action patterns are invariant and are triggered by a neural network called the "innate releasing mechanism" in response to a "sign stimulus" or "releaser" (in this case, the yawns of others act as an innate releasing mechanism; Tinbergen, 1951). Perhaps the phenomenon of *contagious* yawning can be explained by the idea that mimicking the first part of a fixed action pattern (as would be expected if one were mimicking the facial expressions or vocalizations of a conspecific as he or she begins to yawn) is likely to trigger the release of the entire behavior.

In addition to being a form of mimicry, contagious yawning appears to involve an emotional component. Deputte (1994) identified two contexts for yawns: the "rest yawn" observed when the context involves a change in arousal level, and the emotion yawn (which he noted could also be referred to as a "social yawn"). He defined the emotion yawn as an action used as an unconscious communication of psychological decompression after a state of high alert. Yawning is also similar to the other highly contagious acts of crying and laughing, both of which represent emotional states, in that it produces a distinct sound, as well as a distinct facial expression (Provine, 1996). The existence of an emotion yawn suggests that contagious yawning may be considered a form of emotional contagion. On the other hand, yawning may not signal an emotion but may simply be a facial expression that is unintentionally mimicked, as are other nonemotional facial expressions (Heyes, 2001). If so, then its contagiousness may simply be a by-product of ubiquitous facial mimicry, perhaps evolutionarily adaptive because it facilitates contagion of "true" emotions. In either case, the disruption of mimicry, which may be demonstrated by a disruption in contagious yawning, should have consequences for emotional resonance with others. Indeed, empathetic people exhibit greater amounts of all forms of mimicry (Chartrand & Bargh, 1999) and are reportedly more susceptible to contagious yawning (Platek et al., 2003).

Development of Mimicry, Emotional Contagion, and Contagious Yawning

Some capacity for mimicry and emotional contagion appears to be present from birth. Infants as young as 3 hr old execute some behaviors after witnessing them modeled by an adult (Meltzoff & Moore, 1977), most reliably, tongue protrusion (for a review, see Rogers, 2006). Similarly, a case has been made for the presence of emotional contagion from the first days of life; specifically, newborn infants will cry when they hear other babies crying in the nursery, but not in response to computer-generated sounds matched for acoustic properties (Simner, 1971). According to one point of view, newborn "matching" behaviors are early examples of the strong link between the *perception* of actions and emotions in others, and the *experience* of these actions and emotions in ourselves, thus setting the stage for imitative abilities that emerge later and underlie critical aspects of social and emotional development. However, early mimetic behaviors and contagious crying gradually become less frequent after birth. Imitative tongue protrusion disappears by 2–3 months (Abravanel & Sigafoos, 1984), and whereas 84% of newborns exhibit contagious crying, only 24% of 3- to 12-month-old infants do so (Bühler & Hetzer, 1928). In place of full-blown contagious crying, infants at 10–14 months are much more likely to mimic the distressed facial expressions of other crying children (Zahn-Waxler, Radke-Yarrow, & King, 1979). Given these decreases in matching behaviors after 2–3 months, it is unclear whether these early behaviors are continuous with later developing capacities for mimicry and emotional contagion. Mimicry and emotional contagion seem to ''reappear'' during the second half of the 1st year and then continue to expand thereafter. For example, by 9 months, babies take on the basic moods and facial expressions of their caregivers, such as joy and sadness (Termine & Izard, 1988). A longitudinal study by Jones (1996) found that mimicry of distinct actions appeared at distinct periods in development between 6 and 18 months.

Spontaneous yawning (termed the ''rest yawn'' according to Deputte, 1994) begins in utero. In contrast, the limited data on contagious yawning (presumably, the emotion yawn) hint that it may not emerge until much later in development. Piaget (1951) reported that his own children did not begin to yawn contagiously until the 2nd year of life. A more recent study suggested an even later age of emergence for contagious yawning, reporting that only children 5 years and older yawned in response to videos of yawns (Anderson & Meno, 2003). Children respond to live stimuli well before they respond to video stimuli (Troseth & deLoache, 1998), and so in vivo yawning may be a more effective stimulus for eliciting contagious yawning in younger children. Furthermore, the instructions in the Anderson and Meno (2003) study required participants to clap whenever they witnessed a yawn. Clapping is an arousing activity, and increased arousal is associated with diminished yawning (Provine, 2005). In addition, the clapping instructions drew conscious attention to yawning, which has also been shown to diminish yawning (Provine, 2005). For all these reasons, the extant results must be interpreted with caution. Therefore, there are few data to address the developmental course of contagious yawning in typical development.

Mimicry, Emotional Contagion, and Contagious Yawning Deficits in Individuals With ASD

Consistent with the hypothesis that mimicry facilitates emotional contagion (Hatfield et al., 1994), children with autism spectrum disorders (ASD) show deficits in both. McIntosh, Reichmann-Decker, Winkielman, and Wilbarger (2006) found that, unlike controls, adults with high-functioning autism did not unconsciously copy the facial expressions of individuals viewed on a video screen (despite being able to imitate them when asked). Meanwhile, children with ASD have been found to be less susceptible to emotional contagion when provided with prompts that typically elicit emotions that match those of the model: for example, an experimenter opening a box in a child's presence and looking delighted or afraid (Scambler et al., 2006) or an experimenter injuring herself (Bacon, Fein, Morris, & Waterhouse, 1998).

One study has examined contagious yawning in children and adolescents with diagnoses including Autistic Disorder, Pervasive Developmental Disorder, Not Otherwise Specified (PDD-NOS), and Asperger's disorder. Participants with ASD were less susceptible than age-matched typically developing (TD) peers to contagious yawning when exposed to video recordings of people yawning (Senju et al., 2007). Results are difficult to interpret, however, because the ASD group had a lower mental age, and included fewer females, and because of the use of video rather than live models. Given that all these factors could potentially play a role in mimicry, further data are needed to clarify the dimensions of the relative susceptibility of individuals with ASD to contagious yawning.

Current Studies

Study 1 explored the chronological and mental ages at which contagious yawning is exhibited in typical development to provide clues about psychological mechanisms underlying this phenomenon. The study delivered yawning stimuli in an implicit paradigm (i.e., no instructions were given regarding yawning) by a live model, and study procedures were the same for all children—design factors intended to maximize sensitivity to the phenomenon. If contagious yawning is a primitive mimetic response, like contagious crying, it should be evident in the youngest members of the sample. In this case, its reduction or absence in individuals with ASD would imply that basic building blocks of social connection may be abnormal from birth. In contrast, a protracted emergence of contagious yawning would be consistent with the idea that mimicry becomes more ubiquitous and/or fine-tuned as development proceeds. In this case, diminished yawning contagion among individuals with ASD would seem to be a reflection of their diminished implicit social and emotional learning and experience.

Study 2 sought to measure the rates of contagious yawning in a group of children with ASD. This study provided more rigorous diagnosis than Senju et al. (2007), via use of the Autism Diagnostic Observation Scale (ADOS; Lord et al., 2000), excluding children with Asperger's disorder (a variant of the disorder in which language is not affected and potentially involving distinct neural systems; Goodman, 2005), and using live, rather than videotaped, stimuli. In addition, the study sought to examine whether these group differences could be accounted for by differences in mental age, gender, symptom profile, or diagnosis.

Study 1

Method

Participants

Participants were 123 TD children, ages 1–6 years (approximately 20 at each year of age studied), recruited through two local day-care centers. Parents, teachers, and day-care workers were asked to report any known or suspected developmental difficulties for each child. For children age 2 and above, parents or teachers completed the Behavioral Assessment System for Children, Second Edition (BASC–2; Reynolds & Kamphaus, 2004) to screen for any developmental problems. The data of 3 children were excluded—one due to concerns about Tourette's syndrome, one due to coding problems, and one due to lack of attention —for a final sample of 120 children. Sex distribution varied for each year of age with approximately 57% ($n = 68$) of the total sample being female (see Table 1 for gender breakdown by age). The ethnic background of this group was as follows: 3 children were African American, 5 children were Asian, 32 children were Latino, 3 children were multiethnic, and 80 children were Caucasian.

Procedure

A letter describing the study and obtaining consent was sent home to parents. Parents were asked to either fill out a BASC–2 for their child or give permission for the child's teacher to fill out a BASC–2 for the child. Children whose parents consented to the study were taken individually from their classrooms into a quiet room, seated across from the experimenter. After introducing herself and explaining, ''Now we're going to read some stories together, and then you can pick a prize from this basket'' and showing the child the various toy prizes, the experimenter read aloud one to four stories (depending on the child's age and the complexity of the stories) for a total reading time of approximately 12 min (sometimes with a brief break, again dependent upon the child's developmental level). During the first 2 min of reading, the experimenter did not yawn at all. This, in addition to the first few minutes of introductions before reading, was to control for any changes in arousal level that may have occurred when the children sat down to listen to a story. During the last 10 min of reading, the experimenter paused four times to yawn and discreetly recorded on a coding sheet when a child yawned. Approximately 40% of the sessions (49 of 120), randomly selected, were videotaped and coded by two independent raters (who had not assisted in data collection) for reliability.

For coding purposes, contagious yawns were defined as yawns occurring within 90 s of the yawning stimulus. Although subconscious reactions typically occur much more rapidly, previous reports of contagious yawning (e.g., Provine, 2005) indicate that contagious yawning reactions may be somewhat slower and we wanted to allow for the most liberal possible estimate of the phenomenon, as well as for the possibility that yawning contagion may be mediated by some cognitive processes. Because contagious yawning is a low base rate phenomenon, yawning was coded as a dichotomous

Table 1

variable (present or absent) rather than a measure of yawning frequency (number of yawns total). (Analysis of yawning frequency in all statistics examined in Studies 1 and 2 did not yield a different pattern of results.) Children were considered to be contagious yawners if they yawned in response to at least one of the experimenter's four yawns within a 90-s window. (Yawns occurring outside the 90-s window were exceedingly rare, with only two occurring over the 196 videotaped trials.) Coding criteria required the presence of all of the physical manifestations of a yawn (Provine, 2005): open mouth, narrowed eyes, and an indrawn breath. The data of one 3-year-old girl had to be excluded because she covered her mouth and made a sighing sound but her eyes did not narrow at all. Thus, neither the experimenter nor the research assistants were able to determine whether the child was pretending to yawn in order to imitate the experimenter or was truly yawning. Interrater reliability was 100%, when the one ambiguous responder was removed.

Videotaped sessions were also coded for children's looking behavior toward the experimenter during the 10-s segment in which the yawns were presented by assigning each child a rating of 1 *(not looking at all)*, 2 *(looking for less than 5 s of the 10 s block coded)*, 3 *(looking for 5 or more seconds of the 10 s block coded)*, or 4 *(looking throughout the 10 s block in which the yawn stimulus was presented)* for each of the four trials, resulting in a visual attention score of 1–16 for each child. The data of children with scores of less than 12 ($n = 1$ in Study 1) were excluded from analysis.

Results and Discussion

Results showed that, when exposed to the yawns of a live model over four trials, the proportions of children in each age group who yawned contagiously for at least one trial were as follows: 0% (0/20) of 1-year-olds, 5% (1/20) of 2-year-olds, 10% (2/20) of 3-year-olds, 35% (7/20) of 4-year-olds, and 40% (8/20) of both 5- and 6-year-olds (see Figure 1). Binary logistic regression revealed a significant effect for age, $\chi^2(1, N = 120) = 22.254$, $p < .001$, but not for visual attention, $p = .22$, or gender, $p = .37$, in predicting whether or not a child will yawn contagiously at least once across the four trials of the experiment, with each year of age increasing the odds of contagious yawning by a factor of 2.2. However, the data suggest that these variables do not have a linear relation. Thus, age was recoded dichotomously as “under 4 years” or “4 years and over,” $\chi^2(1, N = 120) = 22.69$, $p < .001$, revealing that being 4 years or older increased each child's odds of yawning contagiously by a factor of 14.7 (visual attention and gender remained insignificant).

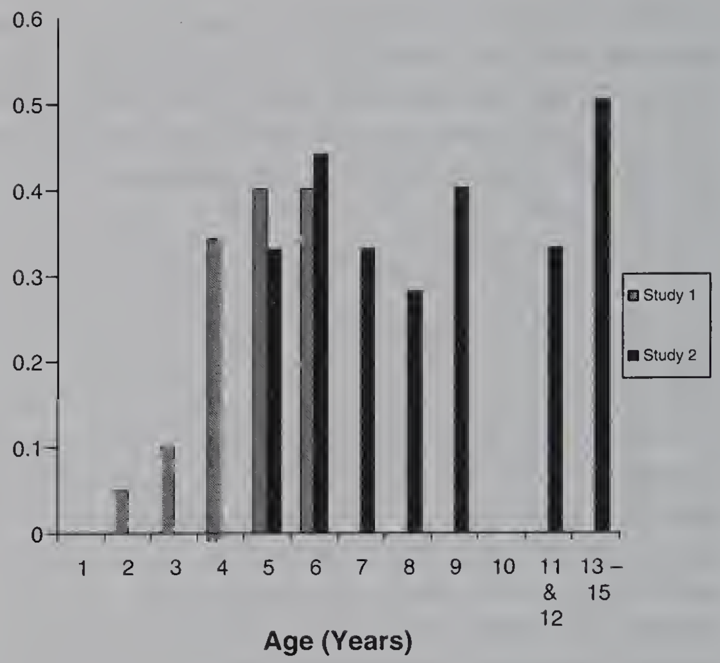

Figure 1. Proportion of contagious yawning by chronological age in typically developing children, Study 1 (children 1–6 years) and Study 2 (children 5–15 years).

Although the older children appeared to make more sustained eye contact in the direction of the experimenter's face and the book throughout the session, the experimenter yawned when she had each child's attention, resulting in good visual attention to the yawns from all age groups (see Table 1). The amount of visual attention that children directed toward the examiner's face was examined in one-way analysis of variance. There was a statistically significant difference in visual attention scores for the six age groups, $p < .01$. Post hoc comparisons indicated that the mean attention score for 1-year-olds was significantly different from that for 5-year-olds, $p < .001$, and 6-year-olds, $p = .02$. In addition, the mean score for the 2-year-olds differed from that for the 5-year-olds, $p < .01$.

These results indicate that children younger than 4 years are significantly less likely than children 4 years and older to yawn after being exposed to the yawn of another. In contrast to Anderson and Meno (2003), who observed no contagious yawning prior to age 5, the present study observed contagious yawning as early as 2 years with a significant shift in frequency at 4 years. The differing results between the present data and those of Anderson and Meno (2003) may be the result of presenting the yawning stimuli in a live, implicit paradigm rather than a video, explicit paradigm. Only a single child exhibited contagious yawning at age 2—the age at which Piaget (1951) observed his children to begin yawning contagiously. Given that individuals tend to engage in more mimicry with individuals with whom they have rapport (Chartrand & Bargh, 1999), parents may elicit contagious yawning in their own children earlier than it can be measured by an unfamiliar experimenter. It is also possible that parents may notice a pattern of earlier onset because they have a much larger window in which to observe their children compared with this relatively brief experiment.

The temporal discrepancy between the emergence of spontaneous (rest) yawning and contagious crying (evident from birth), and that of contagious (social-emotional) yawning, indicate that they may not share a common basis. Rather, this later emergence of contagious yawning suggests that it may build upon early empathic or cognitive development.

Study 2

Method

Participants

Participants were 30 children with a diagnosis of an ASD, in addition to 63 TD children. Diagnosis for the ASD group was confirmed by the experimenter (MH) using the Autism Diagnostic Observation Scale (ADOS) using *DSM–IV* criteria (American Psychiatric Association, 1994); see Table 2 for group characteristics. Fifteen children met criteria for autistic disorder on the ADOS, whereas 13 children met criteria for a milder form of autism (PDD-NOS). PDD-NOS refers to cases in which a child experiences marked impairment in social interaction, as well as difficulties with communication and/or stereotyped behaviors patterns or interests but does not meet full diagnostic criteria for autistic disorder. The ethnic background of this group was as follows: One child was African American, 1 child was Asian, and 28 children were Caucasian.

The two TD groups were matched to children with ASD on either chronological age (within 6 months) or mental age (within 6 months) as well as gender. No TD child was used in both mental age (MA) and chronological age (CA) control groups, and none of the children in Study 2 participated in Study 1. The data of 7 TD children were excluded because they were not matched to the ASD group on these parameters. Children with ASD were recruited via flyers at local autism events whereas TD children were recruited via flyers at local family events. In the TD group, 2 children were Asian, 12 children were Latino, 3 children were multiethnic, and 46 children were Caucasian.

Measures

The Socialization domain of the Vineland Scales of Adaptive Behavior–Interview Edition. The Vineland (Sparrow, Balla, & Cicchetti, 1984) is a semistructured parent interview designed to assess a child's adaptive functioning. This study utilized the Socialization domain. Age-equivalent and standard scores for social skills were used in the present analyses.

Autism Diagnostic Observation Scale. The ADOS (Lord et al., 2000) consists of a structured play session that provides participants opportunities to engage in conversation, narrative, problem-solving,

Table 2
Characteristics of Autism Spectrum Disorder (ASD) and Typically Developing (TD) Control Groups in Study 2

and imaginative tasks. The ADOS is scored according to *DSM–IV* criteria for the autism spectrum diagnoses.

Stanford–Binet Intelligence Scale: Fifth Edition (Roid, 2003). In the Stanford–Binet Abbreviated IQ scales, children provide word definitions, yielding a verbal IQ score, and solve a series of picture puzzles, yielding a performance IQ score. This measure provided an index of MA.

Procedure

Children with ASD and TD children sat across the table from a live examiner. Children were tested in a quiet room in their home or in the University of Connecticut Psychological Services Clinic. After an introduction and discussion of the procedure, the experimenter read each child a story, yawning four times during the story. She then administered the Stanford–Binet and (for the ASD group) the ADOS. Because older children, and those who are fluent readers, may have felt uncomfortable with an adult reading to them, those children were told, ''First, I'm going to read you a story, and then I'll ask you some questions about it'' as opposed to simply, ''First, I'm going to read you a story.'' Thus, 14 of the 28 participants in both the ASD and mental-age-matched typically developing control (MA-TD) groups and 22 of the 28 participants in the chronological-age-matched typically developing control (CA-TD) group were told they would be asked questions following the story. In order to explore whether children with ASD yawned spontaneously (as opposed to contagiously) less often than TD children, the test period of the Stanford–Binet administered after the yawning stimuli were also coded for the presence or absence of yawns.

All story sessions were recorded on videotape and coded for looking and yawning behavior by raters blind to group status using the same coding procedures as in Study 1. Interrater reliability, coded for each block, was 83% for looking behavior and 100% for yawning. After the story and test session, parents completed the socialization portion of the Vineland interview.

Results and Discussion

Children with ASD were significantly less likely than TD children to yawn after being exposed to the experimenter's yawn. Only 11% (3/28) of the children with ASD aged 5–12 yawned, compared with 43% (12/28) of a TD control group matched for CA-TD, Fisher's exact $p = .009$, and 36% (10/28) of a control group matched for MA-TD, Fisher's exact $p = .037$ (see Table 3 for group characteristics). When the ASD group was further divided by diagnosis, it became clear that children diagnosed with autistic disorder were less likely to exhibit contagious yawning than children diagnosed with PDD-NOS, $\chi^2(1) = 3.88$, $p = .05$. Specifically, *none* of the children with autistic disorder ($n = 15$) showed contagious yawning, whereas 23% of the children with PDD-NOS ($n = 13$) did. CA, MA, instruction type, visual attention scores, Vineland socialization scores, and diagnosis were entered into a single binary logistic regression model with contagious yawning as a dichotomous variable. In contrast to the results for younger children (ages 1–6 years) found in Study 1, binary logistic regression on contagious yawning in children ages 5–15 years revealed no main effect for age, $p = .80$ (see Figure 1). These data are consistent with the possibility that the rate of contagious yawning remains relatively stable after 5 years, though the relatively small sample size for the current study prevents us from drawing a firm conclusion. No significant effect was found for instruction type ($p = .83$) or MA ($p = .87$). Surprisingly, no significant effect was found for Vineland socialization scores ($p = .924$). The only significant predictor of contagious yawning was diagnosis ($p = .014$), with the absence of an autism spectrum diagnosis increasing the odds of contagious yawning by a factor of 5.8.

A second binary logistic regression was used on the ASD group data only to determine whether autism symptom severity (as indexed by ADOS scores) showed a relation with contagious yawning. Despite the effect of diagnostic severity on yawning contagion, the results suggested no relation between contagious yawning and total ADOS scores, $\chi^2(1, N = 28) = 1.08$, $p = .30$, or communications ($p = .276$) and socialization ($p = .919$) subscales. A possible explanation for this discrepancy is that although the ADOS is an exceptional

Table 3
Number of Children Who Exhibited Contagious Yawning in Study 2 by Group

	Autistic disorder	PDD-NOS	MA-TD	CA-TD
Yawn	0	3	10	12
No yawn	15	10	18	16
% total	0%	23%	36%	43%

Note. PDD-NOS = Pervasive Developmental Disorder, Not Otherwise Specified; MA-TD = mental-age-matched typically developing control; CA-TD = chronological-age-matched typically developing control.

instrument for diagnosing autism, ADOS scores have not been standardized for the purposes of using it as a continuous measure of autism severity. Indeed, individual items on the ADOS vary with respect to their correlation with both IQ and CA (Gotham, Pickles, & Lord, 2009). It is also likely that the very low rate of contagious yawning in the ASD group may have masked relations between contagious yawning and symptom profiles in this group.

Two children with ASD were excluded from analysis because their visual attention scores fell below 12. For the remaining children, ASD ($M = 14.6$) and TD ($M = 15.1$) groups did not differ significantly, $t = .74$, $p = .14$, on the amount of time spent looking toward the experimenter during the 10 s periods in which the yawning stimuli were presented. As in Study 1, this is likely because the experimenter yawned at times when she was confident that she had the child's attention, not because there are no general differences in visual attention between groups.

Finally, TD children were no more likely to yawn (19.6%) than children with ASD (14.3%) during the nonexperimental portion of the study (such as the Stanford–Binet administration), $\chi^2(1, N = 28) = .091$, $p = .76$. In addition, the experimenter asked the parents of the ASD children whether they believed that their child yawns less frequently than TD children; only one parent responded in the affirmative. Taken together, these data imply that the ASD deficit observed is specific to the contagious, or emotion yawn and does not affect the spontaneous, or rest yawn.

The diminished tendency for participants in the ASD group to yawn contagiously to a live stimulus is consistent with previous findings that individuals with ASD show diminished contagious yawning with a video stimuli (Senju et al., 2007) as well as general deficits in mimicry (McIntosh et al., 2006). The current study is novel in several regards. First, the data demonstrate that individuals with ASD are less likely to yawn contagiously than their TD peers, even when controlling for MA and gender. Second, the magnitude of this difference in autistic disorder is much greater than previously reported, when using live rather than videotaped stimuli. Most importantly, the current data demonstrated a striking effect of diagnosis, with children with autistic disorder being less likely to show contagious yawning than children with PDD-NOS. Autistic disorder is characterized by more marked deficits in the realms of communication, social relatedness, and stereotyped interests and behaviors. Thus, the latter findings indicate a significant relation between diagnostic severity in ASD, and susceptibility to contagious yawning.

At a broad level, the late onset of this phenomenon in typical development implies that an autistic deficit in contagious yawning may be a reflection of a deficit in early social learning that affects the ability or tendency to mimic the actions and emotions of others. Nonemotional sounds and mouth movements, such as mouth opening when feeding a baby, are unintentionally imitated (Heyes, 2001) and modulated by experience (Heyes, 2005). Future research is needed to explore whether these forms of mimicry are unconsciously imitated by children with autism (work that is currently underway in this lab). If they are not, this finding would lend further support to the proposal that there is an autistic deficit in recognizing or acting on the correspondence between oneself and others (an ability that all mimetic and imitative acts depend upon). Alternatively, individuals with autism may demonstrate a specific deficit in mimicking emotional behavior. Indeed, emotion perception is a documented area of weakness for individuals with autism (e.g., Moody, McIntosh, Mann, & Weisser, 2007).

General Discussion

The present study demonstrates that children younger than 4 years are significantly less likely to yawn contagiously when exposed to a live stimulus—that is, after seeing another, nearby person yawn—than children ages 4 years and older. The very early emergence of *spontaneous* yawning (by the end of first trimester of pregnancy) offers an informative contrast to the much later, postnatal development of *contagious* yawning. This developmental lag may reflect the phylogenetic antiquity of the motor act of yawning (demonstrated in most vertebrates) relative to the recent evolution of contagion (convincingly demonstrated only in humans and chimpanzees; Anderson, Myowa-Yamakoshi, & Matsuzawa, 2004). The present study also demonstrates that children with ASD are significantly less likely to yawn contagiously when exposed to a live stimulus than TD children. Furthermore, those with a diagnosis indicative of more severe autistic symptoms (autistic disorder) are significantly less likely to yawn contagiously than those with a diagnosis indicative of milder autistic symptoms (PDD-NOS). Taken together, these studies provide further validation for the distinction between spontaneous (or ''rest'') yawns and contagious (or ''emotion'') yawns, and suggest that contagious yawning is linked with social development.

More research is needed to establish whether contagious yawning is unique or whether all forms of mimicry increase over the course of typical development (potentially with a substantial shift in competence occurring around the age of 4). However, one potential implication of the late onset of contagious yawning in typical development and its near absence among individuals with ASD is that mimicry, and hence emotional contagion, may increase with social experience. It is fairly easy to imagine how mimicry may come to substantially increase during the first years of life. First, it is adaptive for an individual to learn to ''automatically'' experience the emotions displayed on the faces of conspecifics (i.e., experience those emotions without deliberation or analysis). For example, if an individual becomes afraid and retreats upon seeing a predator, it is adaptive for an individual to retreat rather than analyze the situation. Likewise, automatically experiencing a conspecific's disgust may protect an individual from ingesting the same harmful food item (Goldman, 2005).

In the case of yawning, experiencing fatigue along with conspecifics may have served the primary evolutionary function of synchronizing a social group's biological rhythms (Schurmann et al., 2004). Indeed, there is some evidence that social cues alone may sustain shared circadian rhythms in the absence of light (Aschoff et al., 1971). Alternatively, rather than serving a direct evolutionary purpose, contagious yawning may have arisen as a by-product of the automatic tendency to facially mimic others (adaptive in rapidly spreading signals of risk and reward throughout a group).

In addition to facilitating emotional and biological synchronization, mimicry may serve to increase feelings of closeness and connection between individuals (Lakin, Jefferis, Cheng, & Chartrand, 2003). These feelings of affiliation, in turn, increase the amount of mimicry individuals display toward one another (Lakin et al., 2003). This process may escalate in a continuous cycle first between child and parent and, later, child and other members of the community, during the early years of development. Out of such increasingly synchronous bonds may develop abilities such as speech (i.e., Bruner's ''proto-conversations''; Bruner, 1983), joint attention, and deliberate imitation.

It is possible that infants with autism are not able to perceive that they are being mimicked (due to reduced social attention or difficulties with emotion perception) or are unable to mimic accurately (due to difficulties in motor function or self-other mapping), and so synchronization with mother and other members of the social group is less available throughout development. This lack of early mimicry could also affect feelings of psychological connection and opportunities for social learning. These changes could thus leave children with autism unable to recognize primitive socioemotional cues that could otherwise serve to biologically and emotionally synchronize them with people around them.

Speculation About Underlying Neural Mechanisms

Brain imaging studies may hold some promise for shedding light on the neurological substrate of contagious yawning. Two neuroimaging studies have explored contagious yawning by exposing participants to videos of others yawning. One study (Platek, Mohamed, & Gallup, 2005) showed increased activation in the precuneus and posterior cingulate gyrus when participants viewed videos of yawning relative to videos of laughter (another emotionally contagious stimulus). The authors interpreted this activation as evidence that contagious yawning, compared with laughter, involves nonconscious aspects of self-referencing. A second study (Schurmann et al., 2004) found that watching yawn videos elicited activation in a region associated with perception of biological movement—particularly perception of eye and mouth movements (the superior temporal sulcus). In addition, they reported that self-reported desire to yawn was negatively correlated with periamygdalar activation (a region implicated in arousal)—a finding that likely derives from the negative relation between arousal and yawning. Neither study found any special involvement of the *mirror neuron system* (MNS)—a system that is active both when one observes and executes an action—for yawning over and above that recruited for the control stimuli (laughing or neutral faces, and meaningless mouth movements, respectively). An obvious limitation of these studies is that the participants in these studies did not ''catch'' the yawns; they simply reported upon their desire to yawn while viewing the yawning stimuli and thus did not actually experience any form of emotional contagion.

Studies investigating forms of empathy and emotional convergence that more readily lend themselves to neuroimaging have consistently found activation in the insula and anterior cingulate cortex (ACC). We speculate that these areas are likely candidates for distinguishing the neural activation associated with contagious yawning over and above that associated with any type of action (and thus the MNS) including spontaneous yawning or other mouth movements, that is, the regions we speculate underlie the *contagious* component of yawning. Just as the "MNS" may underlie common coding of actions, studies have demonstrated the same common coding in the insula and ACC between first- and third-person experiences of emotional information, such as disgust (Wicker et al., 2003), pain (Singer et al., 2004), emotional body language (de Gelder & Hadjikhani, 2006), and emotional expressions (Carr, Iacoboni, Dubeau, Mazziotta, & Lenzi, 2003). A recent study of children ages 9–10 years supports the involvement of the insula, as well as inferior frontal mirror areas and the amygdala, in the observation and imitation of emotional expressions (Pfeifer, Iacoboni, Mazziotta, & Dapretto, 2008). Furthermore, activation in these areas was associated with the children's empathy levels. In children with autism, activity in these same areas during the observation of emotional expressions has been found to be negatively correlated with symptom severity (Dapretto et al., 2006).

One type of neuron unique to the insula and the ACC is the spindle cell, also known as the Von Economo neuron (VEN). Spindle cells are a late-evolving class of neurons that allow for the conscious monitoring of visceral signals from the body, a process that may underlie the impact of afferent feedback. These neurons do not achieve their ultimate postnatal number until the age of 4 years (the age at which we demonstrate the robust emergence of contagious yawning) and have been reported to be disordered in autism (Allman, Watson, Tetrault, & Hakeem, 2005). VENs are responsible for rapidly extracting statistical probabilities from sensory input based on previous information, giving rise to nonconscious emotional reactions. The more experience we gain, the more we may be able to recognize such patterns and associations, and the more developed these neurons may become. The diminished tendency for contagious yawning in children with ASD could be the result of primary or secondary neurological differences affecting these neurons.

Limitations

While study results were fairly unambiguous, findings are necessarily limited in several dimensions. First, although looking time, or general attention to the experimenter, was accounted for in the present studies, we could not unequivocally verify whether participants were attending to the eye or the mouth region of the speaker; this would have required additional eye tracking methods. This limitation is relevant because Provine (1989) has found that yawning contagion, when elicited by pictures of others yawning, is dependent upon attending to the region of the eyes rather than the mouth. Eye tracking studies have revealed that individuals with autism preferentially fixate on the mouth rather than the eye regions (Klin, Jones, Schultz, Volkmar, & Cohen, 2002), leaving open the possibility that a lack of attention to the *eye region* of others' faces (rather then a deficit in unintentional mimicry) is responsible for diminished yawning contagion in this group. Similarly, as typical children age, they may pay closer attention to the faces of others, resulting in more facial mimicry, and hence, greater emotional and biological attunement with those around them. In contrast, children with autism may never learn to pay closer attention to the faces of those around them, and so their tendency to mimic others, as well as their emotional attunement with others, may not increase over time in the way one observes in typical development. If so, this lack of attention to faces may have a previously unsuspected significance in that it may serve to impair mimicry, resulting in decreased emotional resonance, and perhaps even decreased biological synchrony with others.

An argument against this explanation of the findings is that yawning, like crying and laughing, is a contagious act that produces a sound, and the sound alone is often sufficient to trigger its contagion (Provine, 1996). Indeed, the experimenter in this study produced yawns that included the prototypical auditory accompaniment of an indrawn breath followed by a voiced sigh. In addition, given that there were no significant differences in visual attention to the yawns between the 4-year-olds (the age at which a major susceptibility shift was observed) and the other age groups, the developmental results seem unlikely to be due merely to age-related shifts in visual attention.

Finally, although the low rate of contagious yawning in the ASD group speaks to its significance, it made it impossible to determine the extent to which contagious yawning in this population, when it does occur, is correlated with specific autistic symptoms. If more children with ASD could be found who do yawn contagiously, it might be possible to determine whether such factors correlate with contagious yawning in autism, shedding increased light on the implications of this deficit.

Summary and Conclusions

In order to elucidate the developmental properties of automatic facial mimicry in the form of contagious yawning, we investigated the extent to which groups of children at various stages of social development (TD children ages 1–6, as well as children with ASD) are susceptible to contagious yawning. Findings strongly suggested that children under the age of 4 and children with ASD are less likely to yawn when exposed to another's yawn. The developmental curve associated with the onset of contagious yawning implies that emotional contagion becomes more developed and more sensitive over time, resulting in increased affective attunement with others as children grow older. Meanwhile, individuals with ASD may not experience increased emotional contagion during the early years of development, causing them to be deficient in the automatic emotional reciprocity that psychologically binds most individuals together. More research is necessary to determine what mediates this phenomenon; however, it is possible that in the future contagious yawning may prove to provide a simple measure of automatic facial mimicry, empathy, or perhaps even a biomarker of clinically important neurological characteristics that does not require specialized equipment or testing to detect.

Assessing the Effects of a Work-Based Antipoverty Program for Parents on Youth's Future Orientation and Employment Experiences, Rachel Kaplan, Vonnie C. McLoyd, Kelly Purtell, and Aletha Huston.

Prospective Associations Between Peer Victimization and Aggression, Jamie Ostrov.

Relations Between Physiological and Cognitive Regulatory Systems: Infant Sleep Regulation and Subsequent Executive Functioning, Annie Bernier, Stephanie M. Carlson, Stéphanie Bordeleau, and Julie Carrier.

Reading Minds: The Relation Between Children's Mental State Knowledge and Their Metaknowledge About Reading, Serena Lecce, Silvia Zocchi, Adriano Pagnin, Paola Palladino, and Mele Taumoepeau.

Do Black and Hispanic Children Benefit More From Preschool? Understanding Differences in Preschool Effects Across Racial Groups, Daphna Bassok.

Adolescents' Development of Skills for Agency in Youth Programs: Learning to Think Strategically, Reed Larson and Rachel Angus.

Preverbal Infants Anticipate That Food Will Be Brought to the Mouth: An Eye Tracking Study of Manual Feeding and Flying Spoons, Olga Kochukhova and Gustaf Gredebäck.

Intergenerational Continuity in Child Maltreatment: Mediating Mechanisms and Implications for Prevention, Lisa Berlin, Karen Appleyard, and Kenneth Dodge.

Race Salience and Essentialist Thinking in Racial Stereotype Development, Kristin Pauker, Nalini Ambady, and Evan Apfelbaum.

Differing Levels of Gender Salience in Preschool Classrooms: Effects on Childrens Gender Attitudes and Intergroup Bias, Lacey J. Hilliard and Lynn S. Liben.

Comprehension of Infrequent Subject–Verb Agreement Forms: Evidence From French-Learning Children, Geraldine Legendre, Isabelle Barriere, Louise Goyet, and Thierry Nazzi.

Two-Year-Olds Use the Generic/Nongeneric Distinction to Guide Their Inferences About Novel Kinds, Susan Graham, Samantha Nayer, and Susan Gelman.

Goal Neglect and Working Memory Capacity in 4- to 6-Year-Old Children, Stuart Marcovitch, Janet J. Boseovski, Robin J. Knapp, and Michael J. Kane.

The Social Costs of Academic Success Across Ethnic Groups, Thomas E. Fuller-Rowell and Stacey N. Doan.

Children's Reasoning About Disclosing Adult Transgressions: Effects of Maltreatment, Child Age, and Adult Edentity, Thomas Lyon, Elizabeth A. Ahern, Lindsay A. Malloy, and Jodi A. Quas.

Understanding Bullying and Victimization During Childhood and Adolescence: A Mixed Methods Study, Nancy Guerra, Kirk R. Williams, and Shelly Sadek.

A Developmental Perspective on Executive Function, John R. Best and Patricia Miller.

Pathways to Mathematics: Longitudinal Predictors of Performance, Jo-Anne LeFevre, Lisa Fast, Sheri-Lynn Skwarchuk, Brenda Smith-Chant, Jeffrey Bisanz, Deepthi Kamawar, and Marcie Penner-Wilger.

Development in Children's Comprehension of Linguistic Register, Laura Wagner, Maia Greene-Havas, and Rebecca Gillespie.

How 15 Hundred Is Like 15 Cherries: Effect of Progressive Alignment on Representational Changes in Numerical Cognition, Clarissa Thompson and John Opfer.

Toddlers' Prosocial Behavior: From Instrumental to Empathic to Altruistic Helping, Margarita Svetlova, Sara R. Nichols, and Celia A. Brownell.

A Large-Scale Evaluation of the KiVa Anti-Bullying Program, Antti Kärnä, Marinus Voeten, Elisa Poskiparta, Todd D. Little, Anne Kaljonen, and Christina Salmivalli.

Movement Planning Reflects Skill Level and Age Changes in Toddlers, Yu-ping Chen, Rachel Keen, Kerstin Rosander, and Claes von Hofsten.

Young Children Selectively Avoid Helping People With Harmful Intentions, Amrisha Vaish, Malinda Carpenter, and Michael Tomasello.

Danish Majority Children's Reasoning About Exclusion Based on Gender and Ethnicity, Signe Juhl Moller and Harriet Tenenbaum.

How Does It Look? Level 2 Perspective Taking at 36 Months of Age, Henrike Moll and Andrew Meltzoff.

Emotion Discourse, Social Cognition, and Social Skills in Children With and Without Developmental Delays, Rachel M. Fenning, Bruce L. Baker, and Jaana Juvonen.

A Monozygotic Twin Differences Study of Friends' Aggression and Children's Adjustment Problems, Frank Vitaro, Mara Brendgen, Michel Boivin, Stephane Cantin, Ginette Dionne, Richard E. Tremblay, Alain Girard, and Daniel Perusse.

Gender Differences in Adolescents' Daily Interpersonal Events and Well-Being, Lisa Flook.

Teacher–Child Relationships and the Development of Academic and Behavioral Skills During Elementary School: A Within- and Between-Child Analysis, Carolina Maldonado-Carreño and Elizabeth Votruba-Drzal.

The Effects of the Fast Track Preventive Intervention on the Development of Conduct Disorder Across Childhood, Conduct Problems Prevention Research Group.

Object Similarity Bootstraps Young Children to Action-Based Verb Extensions, Etsuko Haryu, Mutsumi Imai, and Hiroyuki Okada.

The Impact of Enhancing Students' Social and Emotional Learning: A Meta-Analysis of School-Based Universal Interventions, Joseph Durlak, Roger Weissberg, Allison Dymnicki, Rebecca Taylor, and Kriston Schellinger.

Science Does Not Speak for Itself: Translating Child Development Research for the Public and Its PolicyMakers, Jack Shonkoff and Susan Nall Bales.

Domain General Constraints on Statistical Learning, Erik Thiessen.

Reciprocal Relations Between Parenting and Adjustment in a Sample of Juvenile Offenders, Lela Rankin Williams and Laurence Steinberg.

A Randomized Controlled Trial of Child FIRST: A Comprehensive Home-Based Intervention Translating Research Into Early Childhood Practice, Darcy I. Lowell, Alice S. Carter, Leandra Godoy, Belinda Paulicin, and Margaret J. Briggs-Gowan.

Latino Adolescents' Experiences of Discrimination Across the First 2 Years of High School: Correlates and Influences on Educational Outcomes, Aprile Benner and Sandra Graham.

The Generic/Nongeneric Distinction Influences How Children Interpret New Information About Social Others, Andrei Cimpian and Ellen M. Markman.

Two-Year Impacts of a Universal School-Based Social-Emotional and Literacy Intervention: An Experiment in Translational Developmental Research, Stephanie Jones, Joshua Brown, and J. Lawrence Aber.

Conditional Reasoning With False Premises Facilitates the Transition Between Familiar and Abstract Reasoning, Henry Markovits and Hugues Lortie Forgues.

When Easy Comes Hard: The Development of Adaptive Strategy Selection, Rui Mata, Bettina von Helversen, and Joerg Rieskmap.

Coherent Motion Sensitivity and Reading Development in the Transition from Prereading to Reading Stage, Bart Boets, Maaike Vandermosten, Piers Cornelissen, Jan Wouters, and Pol Ghesquière.

Same-Ethnic Friendship Preferences Among German and Turkish Preadolescents Attending Ethnically Heterogeneous Schools, Philipp Jugert, Peter Noack, and Adam Rutland.

Holistic Face Processing in Newborns, 3-Month-Old Infants, and Adults: Evidence From the Composite Face Effect, Chiara Turati, Elisa Di Giorgio, Lara Bardi, and Francesca Simion.

Math-Gender Stereotypes in Elementary School Children, Dario Cvencek, Andrew N. Meltzoff, and Anthony G. Greenwald.

Reporter Discrepancies Among Parents, Adolescents, and Peers: Adolescent Attachment and Informant Depressive Symptoms as Explanatory Factors, Katherine B. Ehrlich, Jude Cassidy, and Matthew J. Dykas.

Urban and Rural Chinese Adolescents' Judgments and Reasoning About Personal and Group Jurisdiction, Charles Helwig, Shaogang Yang, Dingliang Tan, Chunqiong Liu, and Tiffany Shao.

Childhood Trauma and Psychiatric Disorders as Correlates of School Dropout in a National Sample of Young Adults, Michelle V. Porche, Lisa R. Fortuna, Julia Lin, and Margarita Alegria.

The Role of Peer Relationships in the Development of Early School-Age Externalizing Problems, Cristina Sturaro, Pol A. C. van Lier, Pim Cuijpers, and Hans M. Koot.

Relation Between Language Experiences in Preschool Classrooms and Children's Kindergarten and Fourth-Grade Language and Reading Abilities, David K. Dickinson and Michelle V. Porche.

Intergenerational Transmission of Adaptive Functioning: A Test of the Interactionist Model of SES and Human Development, Thomas Schofield, Monica Martin, Katherine Conger, Brent Donnellan, Tricia Neppl, and Rand Conger.

Mentoring in Schools: An Impact Study of Big Brothers Big Sisters School-Based Mentoring, Carla Herrera, Jean Baldwin Grossman, Tina J. Kauh, and Jennifer McMaken.

Remission of Depression in Parents: Links to Healthy Functioning in Their Children, Judy Garber, Jeffrey A. Ciesla, Elizabeth McCauley, Guy Diamond, and Kelly A. Schloredt.

Double Jeopardy: Poorer Social-Emotional Outcomes for Children in the NICHD SECCYD Experiencing Home and Child Care Environments That Confer Risk, Sarah Watamura, Deborah Phillips, Taryn Morrissey, Kathleen McCartney, and Kristen Bub.

Imagining a Way Out of the Gravity Bias: Preschoolers Can Visualize the Solution to a Spatial Problem, Amy Joh, Vikram Jaswal, and Rachel Keen.

Sequential Progressions in a Theory of Mind Scale: Longitudinal Perspectives, Henry Wellman, Fuxi Fang, and Candida Peterson.

Can Maltreated Children Inhibit True and False Memories for Emotional Information? Mark Howe, Sheree Toth, and Dante Cicchetti.

Parents' Involvement in Children's Learning in the United States and China: Implications for Children's Academic and Emotional Adjustment, Cecilia Cheung and Eva Pomerantz.

Four Children and One Toy: Chinese and Canadian Children Faced With Potential Conflict Over a Limited Resource, Doran French, Xinin Chen, Janet Chung, Miao Li, Dan Li, Huichang Chen, and Li Wang.

Influence of Eye Gaze on Spoken Word Processing: An ERP Study With Infants, Eugenio Parise, Andrea Handl, Letizia Palumbo, and Angela Friederici.

Infant and Maternal Sensitivity to Interpersonal Timing, Anne Henning and Tricia Striano.

Emotion Regulation Profiles, Temperament, and Adjustment Problems in Preadolescents, Maureen Zalewski, Liliana J. Lengua, Anna C. Wilson, Anika Trancik, and Alissa Bazinet.

Developmental Pathways to Integrated Social Skills: The Roles of Parenting and Early Intervention in Raising Healthy Children, Catherine Ayoub, Claire Vallotton, and Ann Mastergeorge.

Consequences of "Minimal" Group Affiliations in Children, Yarrow Dunham, Andrew Baron, and Susan Carey.

Revisiting the Impact of Part-Time Work on Adolescent Adjustment: Distinguishing Between Selection, Kathryn C. Monahan, Joanna Lee, and Laurence Steinberg.

Parents as Moderators of the Impact of School Norms and Peer Influences on Aggression in Middle School Students, Albert Farrell, David B. Henry, Sally Mays, and Michael E. Schoeny.

The ABCs of Family Mealtimes: Observational Lessons for Promoting Healthy Outcomes for Children With Persistent Asthma, Barbara Fiese, Marcia A. Winter, and Joanna Corra Botti.

Language Development in Internationally Adopted Children: A Special Case of Early Second Language Learning, Karine Gauthier and Fred Genesee.

Third-Party Social Interaction and Word Learning From Video, Kate O'Doherty, Georgene L. Troseth, Priya Shimpi, Elizabeth Goldenberg, Nameera Akhtar, and Megan M. Saylor.

Computer-Assisted Remedial Reading Intervention for School Beginners at Risk for Reading Disability, Nina Saine, Marja-Kristiina Lerkkanen, Timo Ahonen, Asko Tolvanen, and Heikki Lyytinen.

Desire for Increased Autonomy and Adolescents' Perceptions of Peer Autonomy: "Everyone Else Can; Why Can't I?" Christopher Daddis.

Almost Thinking Counterfactually: Children's Understanding of Close Counterfactuals, Sarah Beck and Carlie Guthrie.

CSRP's Impact on Low-Income Preschoolers' Pre-Academic Skills: Self-Regulation as a Mediating Mechanism, C. Cybele Raver, Stephanie M. Jones, Christine Li-Grining, Fuhua Zhai, Kristen Bub, and Emily Pressler.

Does God Make It Real? Children's Belief in Religious Stories From the Judeo-Christian Tradition, Victoria Cox Vaden and Jacqueline D. Woolley.

Changes in Early Adolescents' Sense of Responsibility to Their Parents in the United States and China: Implications for Their Academic Functioning, Eva Pomerantz, Lili Qin, Qian Wang, and Huichang Chen.

Two- to Eight-Month-Old Infants' Perception of Dynamic Auditory–Visual Spatial Colocation, Gavin Bremner, Alan Slater, Scott Johnson, Uschi Mason, Jo Spring, and Maggie Bremner.

Longitudinal Associations Between Marital Instability and Child Sleep Problems Across Infancy and Toddlerhood in Adoptive Families, Anne Mannering, Gordon Harold, Leslie Leve, Katherine Shelton, Daniel Shaw, Rand Conger, Jenae Neiderhiser, Laura Scaramella, and David Reiss.

Promoting Effective Parenting Practices and Preventing Child Behavior Problems in School, Laurie Brotman, Esther Calzada, Keng-Yen Huang, Sharon Kingston, Spring Dawson-McClure, Dimitra Kamboukos, Amanda Rosenfelt, Ami Schwab, and Eva Petkova.

Age 26 Cost–Benefit Analysis of the Child-Parent Center Early Education Program, Arthur Reynolds, Judy Temple, Barry White, Suh-Ruu Ou, and Dylan Robertson.

Infantile Amnesia Across the Years: A 2-Year Follow-Up of Children's Earliest Memories, Carole Peterson, Kelly L. Warren, and Megan M. Short.

Hemoglobin, Growth, and Attention of Infants in Southern Ethiopia, Nicki Aubuchon-Endsley, Stephanie L. Grant, Getenesh Berhanu, David G. Thomas, Sarah Schrader, Devon Eldridge, Tay S. Kennedy, and Michael Hambidge.

Transition From Crawling to Walking and Infants' Actions With Objects and People, Lana Karasik, Catherine Tamis-LeMonda, and Karen Adolph.

The Genetic and Environmental Covariation Among Psychopathic Personality Traits and Reactive and Proactive Aggression in Childhood, Serena Bezdjian, Catherine Tuvblad, Adrian Raine, and Laura A. Baker.

Structure Mapping and Relational Language Support Children's Learning of Relational Categories, Dedre Gentner, Florencia K. Anggoro, and Raquel S. Klibanoff.

Narrative Elaboration and Participation: Two Dimensions of Maternal Elicitation Style, Gigliana Melzi, Adina R. Schick, and Joy L. Kennedy.

Does Felt Gender Compatibility Mediate Influences of Self-Perceived Gender Nonconformity on Early Adolescents' Psychosocial Well-Being? Meenakshi Menon.

Theory of Mind and Social Interest in Zero Acquaintance Play Situations, Chris Moore, Sandra Bosacki, and Shannon Macgillivray.

Media as Social Partners: The Social Nature of Young Children's Learning From Screen Media, Rebekah Richert, Michael B. Robb, and Erin I. Smith.

Protecting Children From the Consequences of Divorce: A Longitudinal Study of the Effects of Parenting on Children's Coping Processes, Clorinda Velez, Sharlene Wolchik, Jenn-Yun Tein, and Irwin Sandler.

Preschoolers' Quarantining of Fantasy Stories, Rebekah Richert and Erin I. Smith.

Effect of Foster Care on Young Children's Language Learning, Jennifer Windsor, Joann Benigno, Christine Wing, Patrick Carroll, Sebastian Koga, Charles Nelson, Nathan Fox, and Charles Zeanah.

Why Don't Smart Teens Have Sex? A Behavioral Genetic Approach, Kathryn Paige Harden and Jane Mendle.

Preschoolers' Use of Morphosyntactic Cues to Identify Generic Sentences: Indefinite Singular Noun Phrases, Tense, and Aspect, Andrei Cimpian, Trent J. Meltzer, and Ellen M. Markman.

Impaired Acuity of the Approximate Number System Underlies Mathematical Learning Disability, Michele Mazzocco, Lisa Feigenson, and Justin Halberda.

Imitation in Infancy: Rational or Motor Resonance? Markus Paulus, Sabine Hunnius, Marlies Vissers, and Harold Bekkering.

Effects of Nonmaternal Care in the First 3 Years on Children's Academic Skills and Behavioral Functioning in Childhood and Early Adolescence, Sara Jaffee, Carol Van Hulle, and Joseph Rodgers.

Shyness-Sensitivity and Unsociability in Rural Chinese Children: Relations With Social, School, and Psychological Adjustment, Xinyin Chen and Li Wang.

Age Differences in Strategic Planning as Indexed by the Tower of London, Dustin Albert and Laurence Steinberg.

Young Children's Learning and Transfer of Biological Information From Picture Books to Real Animals, Patricia Ganea, Lili Ma, and Judy DeLoache.

Characterizing Children's Expectations About Expertise and Incompetence: Halo or Pitchfork Effects? Melissa Koenig and Vikram K. Jaswal.

Wherein Lies Children's Intergroup Bias? Egocentrism, Social Understanding, and Social Projection, Dominic Abrams.

Can Children With Autism Spectrum Disorders "Hear" a Speaking Face? Julia Irwin, Lawrence Brancazio, Lauren Tornatore, and D. H. Whalen.

The Home Learning Environment Across the First 5 Years: Associations With Children's Vocabulary and Emergent Literacy Skills at Pre-Kindergarten, Eileen T. Rodriguez and Catherine S. Tamis-LeMonda.

A Longitudinal Examination of African American Adolescents' Attributions About Achievement Outcomes, Akilah Swinton, Beth Kurtz-Costes, Stephanie Rowley, and Ndidi Okeke.

Ethnic Stigma, Academic Anxiety, and Intrinsic Motivation in Middle Childhood, Cari Gillen-O'Neel, Diane N. Ruble, and Andrew J. Fuligni.

Examining the Black–White Achievement Gap Among Low-Income Children: Using the NICHD Study of Early Child Care and Youth Development, Margaret Burchinal, Kathleen McCartney, Laurence Steinberg, Robert Crosnoe, Sarah L. Friedman, Vonnie McLoyd, and Robert Pianta.

A Longitudinal Study of Religious Identity and Participation During Adolescence, Anna Lopez, Virginia Huynh, and Andrew Fuligni.

Benefits of Practicing 4 = 2 + 2: Nontraditional Problem Formats Facilitate Children's Understanding of Mathematical Equivalence, Nicole M. McNeil, Emily R. Fyfe, Lori A. Petersen, April E. Dunwiddie, and Heather Brletic-Shipley.

Reciprocal Associations Between Family and Peer Conflict in Adolescents' Daily Lives, Grace Chung, Lisa Flook, and Andrew Fuligni.

The Development of Distrust, Kimberly Vanderbilt, David Liu, and Gail Heyman.

Developing Relationships, Being Cool, and Not Looking Like a Loser: Social Goal Orientation Predicts Children's Responses to Peer Aggression, Karen D. Rudolph, Jamie L. Abaied, Megan Flynn, Niwako Sugimura, and Anna Monica Agoston.

Nonlinear Growth Curves in Developmental Research, Kevin Grimm, Nilam Ram, and Fumiaki Hamagami.

Developmental Continuity in Theory of Mind: Speed and Accuracy of Belief-Desire Reasoning in Children and Adults, Ian Apperly, Frances Warren, Benjamin Andrews, Jay Grant, and Sophie Todd.

Children's Judgments of Emotion From Conflicting Cues in Speech: Why 6-Year-Olds Are So Inflexible, Matthew Waxer and J Morton.

Social-Emotional Effects of Early Childhood Education Programs in Tulsa, William Gormley Jr., Deborah A. Phillips, Katie Newmark, Kate Perper, and Shirley Adelstein.

COGNITIVE SCIENCE

A Multidisciplinary Journal

Journal of the Cognitive Science Society

Executive Editor: Arthur B. Markman

Associate Editors: John R. Anderson • Michael D. Byrne
Susan Goldin-Meadow • Lawrence A. Hirschfeld • Michael D. Lee
James S. Magnuson • Danielle S. McNamara • Johanna D. Moore
Nancy J. Nersessian • Mark A. Pitt • Rajesh Rao • Terry Regier

WILEY-BLACKWELL

COGNITIVE
SCIENCE

Edited by
ARTHUR B. MARKMAN

Published on behalf of the Cognitive Science Society

Cognitive Science publishes articles in all areas of cognitive science, covering such topics as knowledge representation, inference, memory processes, learning, problem solving, planning, perception, natural language understanding, connectionism, brain theory, motor control, intentional systems, and other areas of interdisciplinary concern. Highest priority is given to research reports that are specifically written for a multidisciplinary audience. The audience is primarily researchers in cognitive science and its associated fields, including anthropologists, education researchers, psychologists, philosophers, linguists, computer scientists, neuroscientists, and roboticists.

JOURNAL OF
Personality

Edited by
HOWARD TENNEN

Journal of Personality publishes scientific investigations in the field of personality. It focuses particularly on personality and behavior dynamics, personality development, and individual differences in the cognitive, affective, and interpersonal domains. The journal reflects and stimulates interest in the growth of new theoretical and methodological approaches in personality psychology.

LANGUAGE LEARNING

A Journal of Research in Language Studies

Edited by
NICK C. ELLIS *(General Editor),*
LOURDES ORTEGA *(Journal Editor),*
MARIANNE GULLBERG *(Associate Journal Editor),*
SCOTT JARVIS *(Associate Journal Editor),*
ALISTER H. CUMMING *(Executive Director and Best of Language Learning Series Editor),*
MARY J. SCHLEPPEGRELL *(Monograph Series Editor),*
JOHN H. SCHUMANN *(LL-MPI Cognitive Neuroscience Series Editor)*

Published on behalf of the Language Learning Research Club at the University of Michigan

Language Learning is a scientific journal dedicated to the understanding of language learning broadly defined. It publishes research articles that systematically apply methods of inquiry from disciplines including psychology, linguistics, cognitive science, educational inquiry, neuroscience, ethnography, sociolinguistics, sociology, and semiotics. It is concerned with fundamental theoretical issues in language learning such as child, second, and foreign language acquisition, language education, bilingualism, literacy, language representation in mind and brain, culture, cognition, pragmatics, and intergroup relations. A subscription includes an annual supplement – a volume from the ***Best of Language Learning Series*** or the ***Language Learning Monograph Series*** – as well as a biennial monograph – the ***Language Learning-Max Planck Institute Cognitive Neurosciences Series.***

Notice to Contributors

Child Development publishes empirical, theoretical, review, applied, and policy articles reporting research on child development. Published by the interdisciplinary Society for Research in Child Development (SRCD), the journal welcomes relevant submissions from all disciplines. Further information is available at http://www.srcd.org/cd.html.

Types of Articles

Child Development considers manuscripts in formats described below. Inquiries concerning alternative formats should be addressed to the Editor prior to submission. All submissions are expected to be no more than 40 manuscript pages, including tables, references, and figures (but excluding appendices). Authors should provide a justification if the submission is substantially longer. Unless the editor finds that justification compelling, the submission will be returned to the author for shortening prior to editorial review.

Empirical articles comprise the major portion of the journal. To be accepted, empirical articles must be judged as being high in scientific quality, contributing to the empirical base of child development, and having important theoretical, practical, or interdisciplinary implications. Reports of multiple studies, methods, or settings are encouraged, but single-study reports are also considered. Empirical articles will thus vary considerably in length, but should be no longer than 40 manuscript pages; text and graphics should be as concise as material permits. All modes of empirical research are welcome.

Empirical reports are reserved for short cutting-edge empirical papers that are no longer than 4,000 words in length (including text, tables, footnotes, appendices), which advance research and knowledge in an area through noteworthy findings and/or new methods. For manuscripts that require longer descriptions of methods and results, authors should use the Empirical article format.

Reviews focus on past empirical and/or on conceptual and theoretical work. They are expected to synthesize or evaluate a topic or issue relevant to child development, should appeal to a broad audience, and may be followed by a small number of solicited commentaries.

Essays describe original concepts, methods, trends, applications, and theories; these may also be accompanied by solicited commentaries.

Child Development and ... are articles that provide readers with tutorials about some new concept or academic specialty pertinent to research in child development. These papers should review the major definitions, methods, and findings of the concept or specialty and discuss past or potential links to child development.

From another perspective is a format in which papers on a focal topic, written by different authors, are published simultaneously. Papers represent diverse perspectives (e.g., authors whose work represents different populations; different disciplines; different theories, methods, or analytic tools). In some cases, calls for submissions on particular topics will be disseminated through SRCD (via e-mail or SRCD publications), and submissions will undergo normal editorial review. In some cases, a submitted manuscript (e.g., an empirical article) may be selected as a lead article for this format, with invited commentaries providing additional perspectives. The editors also welcome suggestions from readers for topics for this format.

Manuscript Submission

Child Development invites for consideration manuscripts that are neither identical to nor substantially similar to work published or under review elsewhere. In the submission cover letter, please provide details about other published or submitted papers having substantial overlap (including data sets) with the new CD submission to enable editors to judge whether the new submission is sufficiently distinct from other work to warrant consideration. Please note if the paper is posted on a website, see http://www. srcd.org/web posting. html. Editors retain the right to reject manuscripts that do not meet established ethical standards for research or dissemination.

Manuscripts should be submitted electronically to the Child Development Online Submission Site at www.srcd.org /CDsubmit/ as a Word or WordPerfect file. Please also submit a cover letter that contains the name(s) of the author(s) and affiliation(s), and the street address, telephone, fax, and electronic mail address of the corresponding author. A corresponding author's submission to *Child Development* implies that all coauthors have agreed to the content and form of the manuscript and that the ethical standards of SRCD have been followed (see the *Child Development* website or pp. 283–284 of the 2000 SRCD Directory). Any financial interest or conflict of interest must be explained to the Editor in the cover letter. The corresponding author is responsible for informing all coauthors, in a timely manner, of manuscript submission, editorial decisions, reviews, and revisions. Please note that if your submission (or its revision) is accepted for publication, each author must submit a signed Exclusive License Form (http://www.srcd.org/Documents/Publications/CD/cdcopyright.pdf) before the manuscript can enter production. Planning ahead to meet this requirement is especially important for manuscripts with multiple authors.

The manuscript file should be formatted with double-spaced, 12-point type, and should include a single paragraph abstract of 100–120 words. Please follow all guidelines on format, style, and ethics provided in the Publication Manual (6th ed.) of the American Psychological Association. Figures included with initial submissions will not be returned. Therefore, please submit only electronic files or copies of figures. If color artwork is submitted, and the authors believe color art is necessary to the presentation of their work, the submissions letter should indicate that one or more authors or their institutions are prepared to pay the substantial costs associated with color art reproduction. Authors should keep a copy of all correspondence, files, and figures to guard against loss.

Manuscript Review

If you have any questions about your submission, please inquire at cdev@srcd.org or call (734) 926-0615. Each manuscript is handled by the Editor or an Associate Editor who consults with one or more Consulting Editors and/or ad hoc reviewers who have relevant expertise. To ensure blind review, cover sheets are removed before review; authors should avoid including any other information about identity or affiliation in submissions. Copies of the submission and associated correspondence are retained in the SRCD archives. For accepted manuscripts, authors are required to prepare a 300–500 layperson's summary for public dissemination purposes. Details are provided to authors as part of final processing.

There is no charge for publication in *Child Development* unless tabular or graphic materials exceed 10% of the total number of pages. Charges are also levied for changes in proofs other than correction of printer's errors. Any inquiries relating to charges or business matters (including reprint orders) should be addressed to Wiley-Blackwell, *Child Development*, Production Coordinator, 350 Main Street, Malden, MA 02148, (781) 388-8200.

Inquiries and suggestions regarding editorial policy may be addressed to: Dr. Jeffrey J. Lockman, Editor, *Child Development*, Department of Psychology, Tulane University, 2007 Percival Stern Hall, New Orleans, LA 70118-5698, lockman@tulane.edu. *Please do not send electronic or paper manuscripts to the above address.* Doing so will delay the processing of your manuscript.

Note to NIH Grantees

Pursuant to NIH mandate, Society through Wiley-Blackwell will post the accepted version of Contributions authored by NIH grantholders to PubMed Central upon acceptance. This accepted version will be made publicly available 12 months after publication. For further information, see www.wiley.com/go/nihmandate.

MONOGRAPHS OF THE SOCIETY FOR RESEARCH IN CHILD DEVELOPMENT

Recent

FIRST-YEAR MATERNAL EMPLOYMENT AND CHILD DEVELOPMENT IN THE FIRST 7 YEARS
- *Jeanne Brooks-Gunn, Wen-Jui Han, and Jane Waldfogel* (Serial No. 296, 2010).

DEPRIVATION-SPECIFIC PSYCHOLOGICAL PATTERNS: EFFECTS OF INSTITUTIONAL DEPRIVATION
- *Michael Rutter, Edmund J. Sonuga-Barke, Celia Beckett, Jennifer Castle, Jana Kreppner, Robert Kumsta, Wolff Schlotz, Suzanne Stevens, and Christopher A. Bell* (Serial No. 295, 2010).

A DYNAMIC CASCADE MODEL OF THE DEVELOPMENT OF SUBSTANCE-USE ONSET
- *Kenneth A. Dodge, Patrick S. Malone, Jennifer E. Lansford, Shari Miller, Gregory S. Pettit, and John E. Bates* (Serial No. 294, 2009).

FLEXIBILITY IN EARLY VERB USE: EVIDENCE FROM A MULTIPLE-*N* DIARY STUDY
- *Letitia R. Naigles, Erika Hoff, and Donna Vear* (Serial No. 293, 2009).

MARITAL CONFLICT AND CHILDREN'S EXTERNALIZING BEHAVIOR: INTERACTIONS BETWEEN PARASYMPATHETIC AND SYMPATHETIC NERVOUS SYSTEM ACTIVITY
- *Mona El-Sheikh et al.* (Serial No. 292, 2009).

THE EFFECTS OF EARLY SOCIAL-EMOTIONAL AND RELATIONSHIP EXPERIENCE ON THE DEVELOPMENT OF YOUNG ORPHANAGE CHILDREN
- *The St. Petersburg–USA Orphanage Research Team* (Serial No. 291, 2008).

UNDERSTANDING MOTHER-ADOLESCENT CONFLICT DISCUSSIONS: CONCURRENT AND ACROSS-TIME PREDICTION FROM YOUTHS' DISPOSITIONS AND PARENTING
- *Nancy Eisenberg et al.* (Serial No. 290, 2008).

DEVELOPING OBJECT CONCEPTS IN INFANCY: AN ASSOCIATIVE LEARNING PERSPECTIVE
- *David H. Rakison and Gary Lupyan* (Serial No. 289, 2008).

THE GENETIC AND ENVIRONMENTAL ORIGINS OF LEARNING ABILITIES AND DISABILITIES IN THE EARLY SCHOOL YEARS
- *Yulia Kovas, Claire M. A. Haworth, Philip S. Dale, and Robert Plomin* (Serial No. 288, 2007).

THE PRESERVATION OF TWO INFANT TEMPERAMENTS INTO ADOLESCENCE
- *Jerome Kagan, Nancy Snidman, Vali Kahn, and Sara Towsley* (Serial No. 287, 2007).

CHILDREN'S QUESTIONS: A MECHANISM FOR COGNITIVE DEVELOPMENT
- *Michelle M. Chouinard* (Serial No. 286, 2007).

BEST PRACTICES IN QUANTITATIVE METHODS FOR DEVELOPMENTALISTS
- *Kathleen McCartney, Margaret R. Burchinal, and Kristen L. Bub* (Serial No. 285, 2006).

FOUNDATIONS OF SELF-AWARENESS: AN EXPLORATION THROUGH AUTISM
- *R. Peter Hobson, Gayathri Chidambi, Anthony Lee, and Jessica Meyer* (Serial No. 284, 2006).

OUR CHILDREN TOO: A HISTORY OF THE BLACK CAUCUS
OF THE SOCIETY FOR RESEARCH IN CHILD DEVELOPMENT, 1973–1997
- *Diana T. Slaughter-Defoe, Aline M. Garrett, and Algea O. Harrison-Hale* (Serial No. 283, 2006).

PARENTAL SUPPORT, PSYCHOLOGICAL CONTROL, AND BEHAVIORAL CONTROL:
ASSESSING RELEVANCE ACROSS TIME, CULTURE, AND METHOD
- *Brian K. Barber, Heidi E. Stolz, and Joseph A. Olsen* (Serial No. 282, 2005).

BEING HURT AND HURTING OTHERS: CHILDREN'S NARRATIVE ACCOUNTS
AND MORAL JUDGMENTS OF THEIR OWN INTERPERSONAL CONFLICTS
- *Cecilia Wainryb, Beverly A. Brenl, and Sonia Matwin* (Serial No. 281, 2005).

CHILDHOOD SEXUAL ASSAULT VICTIMS: LONG-TERM OUTCOMES AFTER TESTIFYING IN CRIMINAL COURT
- *Jodi A. Quas, Gail S. Goodman, Simona Ghetti, Kristen Weede Alexander, Robin Edelstein, Allison D. Redlich, Ingrid M. Cordon, and David P. H. Jones* (Serial No. 280, 2005).

THE EMERGENCE OF SOCIAL COGNITION IN THREE YOUNG CHIMPANZEES
- *Michael Tomasello and Malinda Carpenter* (Serial No. 279, 2005).

TRAJECTORIES OF PHYSICAL AGGRESSION FROM TODDLERHOOD TO MIDDLE CHILDHOOD:
PREDICTORS, CORRELATES, AND OUTCOMES
- *NICHD Early Child Care Research Network* (Serial No. 278, 2004).

CONSTRAINTS ON CONCEPTUAL DEVELOPMENT: A CASE STUDY OF THE ACQUISITION OF
FOLKBIOLOGICAL AND FOLKSOCIOLOGICAL KNOWLEDGE IN MADAGASCAR
- *Rita Astuti, Gregg E. A. Solomon, and Susan Carey* (Serial No. 277, 2004).

Child Development

CHILD DEVELOPMENT (ISSN 0009-3920), one of three publications of the Society for Research in Child Development, Inc., is published bimonthly by Wiley Subscription Services, Inc., a Wiley Company, 111 River St., Hoboken, NJ 07030-5774. Periodical Postage Paid at Hoboken, NJ and additional offices.

Postmaster: Send all address changes to *CHILD DEVELOPMENT*, Journal Customer Services, John Wiley & Sons Inc., 350 Main Street, Malden, MA 02148-5020.

Information for Subscribers: *Child Development* is published in six issues per year. Institutional subscription prices for 2010 are: Print & Online: US$670 (US), US$938 (Rest of World), €608 (Europe), £479 (UK). Prices are exclusive of tax. Asia-Pacific GST, Canadian GST and European VAT will be applied at the appropriate rates. For more information on current tax rates, please go to www.wileyonlinelibrary.com/tax-vat. The price includes online access to the current and all online back files to January 1st 1997, where available. For other pricing options, including access information and terms and conditions, please visit www.wileyonlinelibrary.com/access.

Delivery Terms and Legal Title: Prices include delivery of print journals to the recipient's address. Delivery terms are Delivered Duty Unpaid (DDU); the recipient is responsible for paying any import duty or taxes. Legal title passes to the customer on despatch by our distributors.

For more information about Wiley-Blackwell journals, including online access information, terms and conditions, and other pricing options, please visit wileyonlinelibrary.com or contact our customer service department, tel: (800) 835-6770 or +1 (781) 388-8598 (Americas); +44 (0) 1865 778315 (Europe, Middle East, and Africa); or +65 6511 8000 (Asia Pacific). Subscription in 2010 includes three issues of *Monographs of the Society for Research in Child Development* and three issues of *Child Development Perspectives.* Single issues from current and recent volumes are available at the current single issue price from cs-journals@wiley.com. Earlier issues may be obtained from Periodicals Service Company, 11 Main Street, Germantown, NY 12526, USA. Tel: +1 518 537 4700, Fax: +1 518 537 5899, Email: psc@periodicals.com. Volumes 37 to date are available in microfilm from ProQuest Information and Learning, Serials Customer Service Department, 300 North Zeeb Road, Ann Arbor, MI 48106; telephone: (800) 521-0600 x2873.

Electronic Access: The *Child Development* website can be found at www.srcd.org. Abstract information for this journal is electronically available at wileyonlinelibrary.com/journal/cdev. This journal is available online at Wiley Online Library. Visit wileyonlinelibrary.com to search the articles and register for table of contents e-mail alerts.

Access to this journal is available free online within institutions in the developing world through the HINARI initiative with the WHO. For information, visit www.healthinternetwork.org

Journal Customer Services: For ordering information, claims and any enquiry concerning your journal subscription, please go to www.wileycustomerhelp.com/ask or contact your nearest office:

Executive Functioning

Best and Miller (p. 1641) reviewed the research on children's executive functions—cognitive skills that enable children and adolescents to control their thoughts and behavior and to act in a goal-directed manner when they are in a new situation. Their examination goes beyond prior reviews, which focused on preschoolers, to include elementary schoolers and teens. Executive function is a critical part of children's development because it is tied to their ability to regulate impulsive behavior and to perform academically. The authors conclude that a developmental perspective is critical for understanding changes in executive functions and their relations over time, as these abilities emerge early in life—in infancy—and continue to mature through adolescence.

Executive functioning—including such skills as impulse control, working memory, and mental flexibility—allows people to consciously plan and monitor their behavior so they can reach desired goals. Why are some children better at these skills than others? In their longitudinal study of 60 Canadian children at ages 1, 1½, and 2, **Bernier, Carlson, Bordeleau, and Carrier** (p. 1739) find that nighttime sleep plays a role. Children who got most of their sleep at night (as opposed to during the day) at ages 1 and 1½ did better in these skill areas than children who did not sleep as much at night. The findings suggest that infant sleep has an effect on developing brain structures in the first 2 years of life, thereby setting in motion a cascade of neural effects that may have implications for later executive skills.

Research has shown that adults' ability to follow through on instructions (called goal maintenance) is related to working memory capacity—the maximum number of items you can keep active in your consciousness. **Marcovitch, Boseovski, Knapp, and Kane** (p. 1687) ask: Is successful goal maintenance in sixty-five 4- and 6-year-olds related to their working memory capacity, or do children at these ages simply lack the ability to keep rules in mind regardless of their working memory? They conclude that children with higher working memory scores were more likely to maintain goals, suggesting that higher order cognitive ability is built from lower order components, even at this young age. The study demystifies parts of executive function and provides insights into the skills needed to engage in the conscious control of behavior, which is a key aspect of success in life.

Helping Hands

Children begin to behave prosocially—that is, they factor others into their actions—before they turn 2. In a study of 65 mostly White 18- and 30-month-olds, **Svetlova, Nichols, and Brownell** (p. 1814) sought to learn why. The researchers find that emphatic and altruistic ability may not be in place in 1-year-olds, even though some of their behaviors may indicate otherwise. They also find that the same behavior can have different meanings at different periods of children's development, with the meaning of helping, in particular, changing over the first few years to include helping that is instrumental (based on action), empathic (based on emotion), and altruistic (requiring a child to give up something that belongs to him or her). Early prosocial behavior, it appears, develops over the 2nd year as children slowly move from instrumental helping to the more complex ability to understand and act on others' specific needs. The study can help adults understand how to encourage young children to behave prosocially.

Vaish, Carpenter, and Tomasello (p. 1661) asked: When young children act prosocially, do they help everyone equally, or are they less likely to help those with harmful intentions? In two studies, of almost 100 German 3-year-olds, they find: Children as young as 3 helped an adult less not only when they saw that the person harmed another person but also when they saw that the person *meant* to harm another person without causing actual harm. And they helped an adult when that person accidentally caused harm. In finding that children are quite sophisticated and discriminating helpers, the study shows that youngsters are sensitive not only to others' moral behaviors but also to the intentions behind those behaviors.

Aggression and Aggressors

Do young children who are physically victimized—hit, kicked, or pushed—by their classmates learn from these interactions to become more physically aggressive over time? Do preschoolers who are socially excluded by their peers model these behaviors and engage in the same type of aggression later? **Ostrov** (p. 1670) took a longitudinal look at more than 100 preschoolers to conclude that young children who are the victims of aggression become aggressors over the course of a school year, with physical victimization leading to physical aggression and relational victimization leading to relational aggression. By illustrating that children may retaliate in the same way based on the harassment they have been subjected to by peers, the findings can inform intervention programs.

Too Smart to Fit in?

Achievement and social acceptance are both important challenges during adolescence. To what extent do the two clash, with students being ostracized for being smart? **Fuller-Rowell and Doan** (p. 1696), in a longitudinal study of a nationally representative sample of almost fourteen thousand 7th through 12th graders over a year, show that ethnicity and school context are both important factors to consider when addressing this question. African American and Native American teens experienced greater social costs with achievement than Whites or other ethnic groups, even after accounting for various background characteristics. The social costs experienced by African Americans were greatest in higher achieving competitive schools, but only when there were not a substantial number of same-race peers at the schools. Similar effects were found for students of Mexican descent. The study, the first to quantitatively show differential social costs with academic success across ethnic groups, points to the significance of issues of race and inequality in schools and can inform programs to address these issues.

Full Disclosure

In one of the first studies to address how children think about telling others about adults' wrongdoing, **Lyon, Ahern, Malloy, and Quas** (p. 1714) focused on maltreated children (children who had suffered from neglect and/or physical or sexual abuse and had been removed from their parents' custody), contrasting their attitudes with a comparable group of children with no history of maltreatment. They asked almost 300 children aged 4–9 to discuss stories that involved adult wrongdoing. Even the youngest (4- and 5-year-olds) distinguished between wrongdoers who were parents and those who were strangers, more often telling when the wrongdoer was a stranger. Older children (8- and 9-year-olds) were more likely to tell one parent about the other parent's wrongdoing, keeping the information in the family. The maltreated children acted somewhat differently, with younger children disclosing less; older maltreated children disclosed more, showing less protectiveness toward parents who had done wrong than children who had not been maltreated—perhaps because of their growing distrust of their parents. The study has implications for legal proceedings involving children.

Building Blocks of Math Knowledge

Can we tell how well children will learn mathematics before they even start first grade? Does early math knowledge predict later math performance? In a longitudinal study, **LeFevre et al.** (p. 1753) tested the math abilities of more than 180 Canadian children aged 4 through 6, then tested them again 2 years later. The researchers find that three kinds of cognitive skills—quantitative, linguistic, and attentional—were related to children's early number knowledge and basic mathematical skills, and these early skills predicted how children did on tasks that assessed conventional math knowledge 2 years later. The results provide a framework for understanding the early links between children's cognitive skills and the development of mathematics knowledge. As such, they can help teachers better understand how children learn math.

According to the National Mathematics Advisory Panel, fostering children's number sense should be made a high priority. The problem is that numbers are infinite, but improvements in number sense typically occur gradually for larger numbers. To address this problem, **Thompson and Opfer** (p. 1768) investigated whether the piecemeal nature of typical number sense development could be exploited to induce broad and rapid changes in number sense. They find that with progressive alignment—when a small numeric range (such as 0–100) for which children had already produced accurate estimates was aligned with large numeric ranges (such as 0–1,000)—children drew analogies between the small and large ranges, and this led them to note deeper commonalities (such as the underlying structure of the decimal system) and produce more accurate estimates for numbers as high as 100,000. This suggests that when instruction is tailored to support analogies, children's existing knowledge about numbers can serve as a foundation for more advanced numerical understanding.

Effects of Preschool by Race

Recent research suggests that the effects of preschool on young children's cognitive development vary by race, with Black and Hispanic children showing greater benefits than their White peers. **Bassok** (p. 1828) conducted a study based on new information on about 7,400 children who were part of the Early Childhood Longitudinal Study, a nationally representative data set that tracks children from birth to kindergarten. She finds that on average, poor 4-year-olds benefit substantially from preschool participation and they do so at about the same rate, regardless of their racial and ethnic background. In contrast, among nonpoor children, the effects of preschool participation differ across groups, with Black children experiencing the biggest boosts. As the number of 4-year-olds in state preschool programs rises, this study can inform the development of programs to help narrow achievement gaps between races.

Hand and Mind

Even 6-month-olds can anticipate goals of manual actions with which they are familiar. That's what **Kochukhova and Gredebäck** (p. 1729) find in their study of infants' ability to anticipate the goal of such actions as feeding and combing hair. Using eye-tracking technology, the researchers sought to determine if infants looked at the goal of the action before it was completed. Based on their finding that babies are better able to anticipate actions involved in feeding (an activity with which they are familiar) than the actions involved in combing hair (an activity with which they are unfamiliar), the researchers conclude that the babies can visually anticipate activities with which they have experience. Furthermore, they find that this ability improves with age—10-month-olds were faster than 6-month-olds. The study, which involved more than 100 babies, sheds light on how infants perceive others' actions.

When children are figuring out how to use motor skills—learning to reach, grasp, and walk—they are also sequencing several motor acts to achieve complex goals. But they're also advancing cognitively, based on a longitudinal study in which children performed a precise task (tower building) and an imprecise task (putting blocks in a large container) by **Chen, Keen, Rosander, and von Hofsten** (p. 1846). Toddlers (aged 18–21 months) do not just carry out actions in isolation, they conclude, but rather actively plan their actions in advance, evaluating the precision demands of the task and adjusting their movement patterns accordingly. A year later, the authors find that the children had matured in their use of arm and hand movements, and individual differences in the speed of some of these movements remained the same. By drawing attention to the interplay between motor skills and cognitive ability, this study offers insights into toddlers' thought processes as they plan movements for tasks with different precision requirements.

Preschoolers' Concepts of Gender and Race

In many preschool classrooms, gender is very noticeable—think of the greeting, "Good morning, boys and girls" or the instruction, "Girls line up on the left, boys on the right." Do such environments promote children's stereotyped views of what activities and jobs are appropriate for boys and girls? Do they affect children's interest in playing with children of the other sex? **Hilliard and Liben** (p. 1787) evaluated more than fifty 3- to 5-year-olds over 2 weeks; in one set of classrooms, teachers continued to avoid making divisions by sex. In the other, teachers used gendered language and divisions (like asking boys and girls to post their work on separate bulletin boards) but still avoided statements comparing boys and girls or fostering competition between them. Children in the classrooms in which teachers avoided characterizations by sex showed no change in responses or behaviors, but children in the other classrooms had more stereotyped attitudes, said they were less interested in playing with children of the other sex, and were observed to play less with these children. By highlighting the powerful effect of classroom environments on children's gender-related beliefs and behaviors, the findings have implications for how teachers interact with children.

Knowledge of racial stereotypes can have important consequences for children: Stereotypes affect children's treatment of others and shape expectations about their own capacity for achievement. In a study of almost 90 mostly European American children aged 3–10, **Pauker, Ambady, and Apfelbaum** (p. 1799) find that children begin applying racial stereotypes at around age 6, particularly those involving individuals of a race different than their own. In addition, two key factors predict whether they use stereotypes—their ability to group others by race and their tendency to think about race as a permanent quality. By teaching children that even though a person's skin color usually cannot be changed, race does not convey stable information about a person's traits, they might be less likely to stereotype others and less susceptible to stereotypes themselves.

Language Learning and Learning About Language

Many languages encode a difference between singular and plural reference. English, for example, encodes singular nouns in one way (a boy) and plurals in another (some boys); verbs also reflect this difference. Little is known about how and when young learners understand this linguistic feature. **Legendre, Barrière, Goyet, and Nazzi** (p. 1859) carried out two experiments with about 75 French children (aged 2 and 2½) learning French. They find that children as young as 2½ (much earlier than previously thought) understand the difference between singular versus plural verb forms in the absence of any other verbal cue. The study helps define the normal course of learning a native language, which can help us understand and identify possible language-related deficits that might not otherwise be detected.

When you're involved in a conversation, you use different linguistic styles depending on whom you're talking to, with the same person speaking differently to a teacher than to a baby, for example. In a study of more than 50 mostly White 3- to 5-year-olds, **Wagner, Greene-Havas, and Gillespie** (p. 1678) sought to determine when children understand that the way people speak provides information about the person they're speaking to. Findings: Around age 4, children can listen to how someone speaks to figure out whom they are speaking to, and this ability continues to improve with age. This suggests that preschoolers are quite sophisticated in their understanding of language and social contexts: Even before they have started formal schooling, they have already learned how others signal their social relationships through subtle shifts in their linguistic style.

Reading Minds

Part of what makes us human is our ability to understand that people's behavior is motivated by what goes on in their minds. This understanding is referred to as mental state knowledge, or the awareness that mental states such as memories, beliefs, desires, and intentions govern people's behavior. **Lecce, Zocchi, Pagnin, Palladino, and Taumoepeau** (p. 1876) wanted to know how young children's knowledge about mental states relates to their understanding of how the mind works when they are older. In their study of more than one hundred fifty 7- to 10-year-olds in Italy, they examined the relation between children's knowledge of mental states and their later understanding of the reading process. They find a genuine link between children's knowledge of mental states (also known as theory of mind) and their metaknowledge about reading (their ability to understand the process of understanding text) that is causal (going from earlier mental state knowledge to later metaknowledge about reading). And they suggest that this relation is specific to children's knowledge about beliefs rather than emotion. The study has implications for educators.

Face Processing

Research on infants' reactions to faces addresses a controversial question: Is sensitivity to faces a special ability in humans? If so, how does it develop? Turati, Di Giorgio, Bardi, and Simion (p. 1894) used an innovative technique to explore whether sensitivity to faces in newborns and 3-month-olds is determined by processing the whole face (holistic processing) or individual components of the face (feature processing). Like adults, 3-month-olds recognized a face relying mainly on holistic information. Newborns, however, did not show evidence of holistic processing, which is consistent with the notion that face processing develops over time rather than exists fully formed at birth.

A Developmental Perspective on Executive Function

John R. Best and Patricia H. Miller
University of Georgia

This review article examines theoretical and methodological issues in the construction of a developmental perspective on executive function (EF) in childhood and adolescence. Unlike most reviews of EF, which focus on preschoolers, this review focuses on studies that include large age ranges. It outlines the development of the foundational components of EF—inhibition, working memory, and shifting. Cognitive and neurophysiological assessments show that although EF emerges during the first few years of life, it continues to strengthen significantly throughout childhood and adolescence. The components vary somewhat in their developmental trajectories. The article relates the findings to long-standing issues of development (e.g., developmental sequences, trajectories, and processes) and suggests research needed for constructing a developmental framework encompassing early childhood through adolescence.

Broadly defined, executive functions (EFs) encompass those cognitive processes that underlie goal-directed behavior and are orchestrated by activity within the prefrontal cortex (PFC; e.g., Olson & Luciana, 2008; Shimamura, 2000). Children's EF has been of great interest to developmental psychologists in recent years. However, this research has three limitations that pose difficulties for constructing a truly developmental account of EF. First, most research on the development of EF has examined narrow age ranges, for example, 2–5 (Isquith, Gioia, & Espy, 2004). Second and relatedly, most research has focused on preschoolers (e.g., Carlson, 2005; Garon, Bryson, & Smith, 2008), perhaps because rapid improvements occur during the preschool and early school years on EF tasks (e.g., Carlson & Moses, 2001; Zelazo, Muller, Frye, & Marcovitch, 2003). However, performance on other, more complex tasks does not mature until adolescence or even early adulthood (e.g., Anderson, 2002; Conklin, Luciana, Hooper, & Yarger, 2007; Davidson, Amso, Anderson, & Diamond, 2006; Luciana, Conklin, Hooper, & Yarger, 2005; Romine & Reynolds, 2005). Moreover, the rudiments of EF emerge before early childhood, likely within the 1st year of life (e.g., Diamond, 1990a, 1990b). Third, we have little information about the processes by which children move from one level to another, especially processes operating after age 5.

Consequently, despite the large literature on EF in children, we have no truly developmental account of EF across childhood and adolescence. The purpose of this article is to begin to construct such an account, which distinguishes it from previously published reviews of EF (but see Best, Miller, & Jones, 2009). We focus on the few studies that include a large age range in an attempt to outline the broad developmental trajectories of EF and look at the development of EF within the framework of developmental theoretical issues.

After a brief presentation of theoretical and methodological challenges to a developmental account of EF, the main part of the review examines changes in three components of EF across multiple ages. Then we address developmental trajectories, sequences of the components, and mechanisms of development, and suggest future research to examine basic issues of development.

Theoretical and Methodological Challenges

Beyond the limitations of narrow age ranges and few studies examining developmental sequences and mechanisms, it is very difficult for other reasons to extract a general trajectory of EF development

from the literature. A main challenge is the lack of agreement concerning whether EF is a unitary construct or a set of independent components (e.g., Barkley, Edwards, Laneri, Fletcher, & Metevia, 2001; Brocki & Bohlin, 2004; Isquith et al., 2004; Miyake et al., 2000). One prominent theoretical framework integrates these opposing perspectives by suggesting that the EF construct consists of interrelated, but distinct, components—described as the ''unity and diversity of EF'' by Miyake et al. (2000). In their seminal study with young adults, Miyake et al. used confirmatory factor analysis (CFA) to test this framework. The CFA extracted three correlated latent variables from several commonly used EF tasks. These latent variables represented three EF components—inhibition, working memory (WM), and shifting—that contributed differentially to performance on complex EF tasks (Miyake et al., 2000; although Miyake recently—2009—has questioned whether inhibition can be considered a distinct component). Thus, although bound by some common underlying processes, in young adults EFs are distinguishable and are employed differentially based on the task at hand.

Some research with children has investigated the EF construct and has found at least partial support for an integrative framework. Hughes (1998) sought to expand a previous finding that EF consists of dissociable components in older children (Welsh, Pennington, & Groisser, 1991). She extracted three distinct factors—attentional flexibility, inhibitory control, and WM—from preschoolers' performance on several EF tasks, suggesting that EF components are differentiated even at a young age. Both Hughes and Welsh et al. (1991) emphasize the independence of these factors, leaving little discussion of whether these factors may be interrelated. Senn, Espy, and Kaufmann (2004), also with preschoolers, used path analysis, which forms each latent variable by drawing on only one task rather than multiple tasks (which makes it more susceptible to extraneous influences such as test order and task reliability that may affect relations among the measures). Although performance on the WM and inhibition tasks was correlated and predicted complex task performance, shifting performance was unrelated to the other measures. This provided evidence that the EF components are dissociable in early childhood but also that those components are interrelated to some degree.

CFA with older children seems to provide stronger support for Miyake's ''unity and diversity view.'' First, Lehto, Juujärvi, Kooistra, and Pulkkinen (2003) found that Miyake's three-factor model provided the best fit of data from children aged 8 to 13. Second, Huizinga, Dolan, and Van der Molen (2006) employed CFA in a more developmental fashion by comparing the models of 7-, 11-, 15-, and 21-year-olds. They found partial support for the Miyake model as only the WM and shifting measures loaded onto latent variables, whereas the inhibition measures did not load onto a common latent variable (see also Miyake, 2009, for similar results with adults). Importantly, this model was consistent across the age groups, suggesting the stability of the EF construct across middle childhood, adolescence, and early adulthood. Together, these studies provide considerable evidence that Miyake's integrative model of interrelated, yet dissociable, EF components may be a suitable theoretical framework from which to examine EF development. However, these studies also suggest that the degree of unity and independence of the three components may change developmentally. This more complete picture of development and more nuanced version of the Miyake et al. model would be missed by focusing on only adults or a narrow age range on children, during the preschool years.

When a sample does include older school-age children and adolescents, methodological challenges can arise. First, to avoid ceiling effects researchers often use complex EF tasks that likely tap into multiple EFs, a problem of task impurity (Miyake et al., 2000). For complex tasks like the Wisconsin Card Sorting Test (WCST), the Tower of London (TOL), or Tower of Hanoi (TOH), task completion likely requires the coordination of multiple processes (e.g., Asato, Sweeney, & Luna, 2006; Huizinga et al., 2006; Miyake et al., 2000). However, for simplicity, researchers often classify tasks by a single cognitive construct. For example, the WCST and its child-appropriate version (DCCS) have been described as inhibition tasks by some and shifting tasks by others (Garon et al., 2008); the TOL and TOH have been described as either inhibition, WM, or planning tasks in various publications (e.g., Berg & Byrd, 2002; Huizinga et al., 2006; Welsh, Satterlee-Cartmell, & Stine, 1999).

Second, and very much relatedly, the tasks used across an age range often are not uniform. Tasks too difficult for the younger participants sometimes are only administered to the older ones, which makes comparisons across age groups difficult (e.g., Klenberg, Korkman, & Lahti-Nuuttila, 2001). Or very different tasks are used to assess a particular dimension for preschoolers and older children (e.g., Hughes, 1998; Welsh et al., 1991).

Keeping these issues in mind, we utilize Miyake's ''unity and diversity'' theoretical framework to focus on the ''foundational'' EFs—inhibition, information updating, and monitoring (WM), and shifting (Hughes, 1998; Huizinga et al., 2006; Lehto et al., 2003; Miyake et al., 2000)—in part because several frequently used cognitive tasks ostensibly tap into each dimension (Miyake et al., 2000). In using this framework to address EF development from early childhood through adolescence, we keep in mind current developmental theories of EF. In general, most of these theories depict EF development as involving an increasing ability to resolve conflict. They differ in whether this conflict is between rules that eventually become hierarchically organized (Zelazo et al., 2003), latent and active representations (e.g., habits vs. attention and WM; Munakata, 2001), or the current representation versus prepotent mental sets or behaviors (Diamond, 2006). Most also emphasize the role of changes in underlying neural networks. In particular, Posner and Rothbart (2007; see also Garon et al., 2008) propose that the development of the anterior attention system plays the major role in the resolution of conflict by regulating other brain networks. Posited developmental change is both qualitative (e.g., changing from simpler to more complex rule systems; Zelazo et al., 2003) and quantitative (e.g., strengthening active representations so that they override latent representations; Munakata, 2001).

We focus on those studies that most clearly address developmental issues—those that examine both preschoolers and school-age children, or school-age children and adolescents; address the order of acquisition of different aspects of EFs; or examine possible developmental processes. This approach permits us to detect developmental trajectories, sequences, and processes. Given a recent extensive review (Garon et al., 2008) of the large literature on the preschool age, only representative studies of this age are included.

Converging evidence and multiple levels of analysis are provided by studies using neuroscience techniques (e.g., functional magnetic resonance imaging [fMRI], event-related potential [ERP]) that assess the neural response underlying EF. It has been known for years that patients with PFC damage can have EF deficits yet normal IQ (e.g., Stuss & Benson, 1984). More recent thinking about this is that the PFC coordinates posterior cortical and subcortical brain activity via excitatory and inhibitory pathways (Casey, Amso, & Davidson, 2006; Shimamura, 2000). Moreover, PFC activity holds relevant information in WM (e.g., ''the cracker is hidden under the left cup'') and prevents distracting information from entering WM (Goldman-Rakic, 1987; Olson & Luciana, 2008; Shimamura, 2000).

We also know from structural imaging studies (e.g., using MRI) that PFC development, like brain development more generally, consists of both progressive (e.g., myelination, neuron proliferation, synaptogenesis) and regressive (e.g., cell death, synaptic pruning; Casey et al., 2006; O'Hare & Sowell, 2008) changes. The PFC matures later in adolescence as evidenced by further loss of gray matter (Gogtay et al., 2004; O'Hare & Sowell, 2008), unlike many other brain regions that mature earlier (e.g., regions involved in attention, motor and sensory processing, and speech and language development). During this time, progressive and regressive changes (largely myelination and synaptic pruning, respectively) occur concomitantly and are driven in part by the child's experiences—the result being ''efficient networks of neuronal connections'' (O'Hare & Sowell, 2008, p. 24).

Developmental neuroscience studies can enrich our understanding of EF development by determining how the neural correlates of behavior change over time. Changes in neural correlates (i.e., the neural response underlying task execution), in turn, can be interpreted in light of the known structural development of the brain and of the PFC in particular. Alternatively, changes in brain structure can be correlated with changes in task performance to determine the relevance of structural changes to EF maturation. In either case, we must remember that both progressive and regressive structural changes may influence how the neural response changes over time.

Foundational Executive Functions

Inhibition

Inhibition is considered foundational for EF (e.g., Miyake et al., 2000); however, most inhibition tasks are not pure measures of inhibition (Simpson & Riggs, 2005) nor do they tap into a single inhibitory process (Nigg, 2000). Garon et al. (2008) distinguished simple from complex response inhibition tasks based on whether WM also is needed. Simple response inhibition requires a minimal amount of WM, making it one of the purest forms of inhibition (Cragg & Nation, 2008). It shows its rudiments during infancy (see Garon et al., 2008), as when a child can delay eating a treat. Complex response inhibition also requires substantial WM by requiring that an arbitrary rule be held in mind or by requiring that the child inhibit one response (prepotent or not) and produce an alternative response. The day-night task assesses complex response inhibition by requiring the child to inhibit a prepotent verbal response (i.e., saying ''day'' upon viewing a picture of a sun) and activate an alternative verbal response (i.e., saying ''night'' upon viewing a sun; Gerstadt, Hong, & Diamond, 1994). Similarly, Carlson and Moses (2001), using factor analysis, distinguished delay tasks, which require withholding a propotent response, from conflict tasks, which require the child to make a response that conflicts with a prepotent response. Thus, the day-night task and Luria's hand game are considered conflict tasks (as well as complex response inhibition tasks) because they require the child to respond in a way conflicting with the natural response (i.e., associating a picture of the sun with night time and making a fist when shown fingers, respectively). Finally, Nigg (2000) distinguished several forms of inhibition that cover cognitive, behavioral, and emotional regulation.

Age differences. Garon et al. (2008) described rapid improvements in early childhood on a variety of complex response inhibition tasks (i.e., conflict tasks), such as the day-night task and Luria's hand game (see also Carlson & Moses, 2001; Hughes, 1998; Lehto & Uusitalo, 2006; Sabbagh, Xu, Carlson, Moses, & Lee, 2006). Despite their apparent similarities, different conflict tasks show different ages of mastery, perhaps indicating different cognitive demands. For Luria's hand game, which requires children to make a fist when shown a finger and vice versa, the most improvement typically occurs between ages 3 and 4 (Hughes, 1998); however, for the day-night task, 3- and 4-year-olds find it equally difficult (Carlson, 2005) and improvements may continue into middle childhood (Gerstadt et al., 1994). Furthermore, preschool children perform better on Luria's tapping task than the day-night task (Diamond & Taylor, 1996). Like Luria's hand game, the tapping task requires the inhibition and activation of hand motor responses, whereas the day-night task requires the inhibition and activation of verbal responses. In addition to different response modalities, Diamond and Taylor (1996) argue that the two tasks differ in the degree of response prepotency: There is a stronger tendency to say ''day'' when shown a sun than to mimic the motor movement of another person. However, evidence of a mirror neuron system that facilitates the imitation of hand gestures (e.g., Iacoboni & Dapretto, 2006) calls into question whether inhibiting the mimicking of hand movements is necessarily easier. In any case, preschoolers have some ability, although still immature and sensitive to task demands, to override a naturally prepotent response in favor of an alternative.

The Dimensional Change Card Sort (DCCS) is another complex response inhibition task used frequently with preschool children. Rather than requiring the inhibition of a naturally prepotent response, the DCCS creates a prepotent response during the preswitch phase that must later be inhibited. The child is shown a deck of cards that vary on two dimensions—shape (e.g., rabbit vs. battleship) and color (e.g., red vs. blue). During the preswitch phase, the child must sort the cards according to one dimension (e.g., color; ''If it's red, it goes here; if it's blue, it goes here''). In the postswitch phase, the child is asked to sort the cards by the other dimension (e.g., shape). Similar to other conflict tasks, reductions in perseveration occur from ages 3 through 4 (Carlson, 2005; Zelazo et al., 2003).

Manipulations of the standard DCCS provide insight into the developmental sequence of inhibition (e.g., Zelazo, 2006; Zelazo et al., 2003). In a No Conflict DCCS, the inhibitory demands are minimized, but the WM demands are maintained by presenting four nonoverlapping rules by which to sort the cards (e.g., sort by two colors at preswitch and by two shapes at postswitch). Here, 3- and 4-year-olds perform equally well, suggesting that the WM demands by themselves are not the cause of difficulty for the younger children in the standard DCCS (Zelazo et al., 2003). In an Advanced DCCS, a third sorting dimension is added; if there is a star on the card, the child should sort by color, but if there is not a star, the child should sort by shape. Five- and six-year-olds find this task difficult, showing a < 50% chance of passing (Carlson, 2005). Thus, as predicted by Zelazo's cognitive complexity and control (CCC) theory (Zelazo et al., 2003), the complexity of a task, defined in terms of the hierarchical structure of the child's rule system, is critical to task performance. The complexity of the child's rule system increases as the child integrates and embeds seemingly incompatible rules based on color and shape: ''If sorting by color, the blue one goes here; if sorting by shape, the rabbit goes here.'' An inability to integrate the rule systems causes perseverative errors; that is, the child will continue to sort the cards based on the initial dimension—color or shape. The Advanced DCCS requires the integration of another rule based on the presence of a star, whereas the No Conflict version does not require the integration of any rules—supporting the notion that the integration of rules is critical for inhibition development.

Findings of further improvement in inhibition after age 5 are mixed. In a rare study examining a wide age range, Klenberg et al. (2001) found improvement from ages 3 to 6 on the Statue task (maintaining a body position while the experimenter attempts to distract the child) and the Knock and Tap game (e.g., tap when the experimenter knocks and vice versa), but no further significant improvement through age 12. However, these tasks may have been too easy for the older children—perhaps because of the low prepotency of the response to be inhibited. A similar problem of finding appropriate tasks when using a wide age range is that the cognitive battery used in this study, the NEPSY, contains subtests not suitable for the youngest children. Thus, the 3- and 4-year-olds only completed 3 of the possible 12 subtests, making comparisons across the entire age range difficult. Still, in support of the conclusion that inhibition stabilizes by the early school years, Lehto et al. (2003) found no significant changes in inhibition between ages 8 and 13 on the TOL and Matching Familiar Figures tasks (although the inhibitory aspects of these tasks are not clearly identified, and see Steinberg et al., 2008, for continued improvements in an impulsivity measure of TOL performance through adolescence and early adulthood).

Other studies find further development after age 8. Interestingly, many of these studies have utilized computerized tasks such as the Go-No-Go task or the continuous performance task (CPT), both of which require a response to certain stimuli and inhibition of response to other stimuli (Brocki & Bohlin, 2004; Casey et al., 1997; Cragg & Nation, 2008; Johnstone et al., 2007; Jonkman, 2006; Jonkman, Lansbergen, & Stauder, 2003; Lamm, Zelazo, & Lewis, 2006). In the Go-No-Go computer task, the child must respond (by pressing a designated keyboard button) only to "go" stimuli (e.g., all letters except *X*) and inhibit response to the "no-go" stimulus (e.g., the letter *X*). The CPT adds a cue prior to go and no-go stimuli. For example, the child may be asked to respond to the letter *X*, but only when preceded by the letter *A*. Thus, responding to a no-go stimulus is considered a failure of inhibition ("commission errors"). Unlike conflict tasks, these tasks do not require the execution of an alternative response.

In one of these studies (Brocki & Bohlin, 2004), significant improvements occurred from ages 7 to 9 to 11 on behavioral measures that loaded onto a factor that the authors labeled a "disinhibition" factor (CPT disinhibition, CPT impulsivity, CPT inattentive impulsivity, and Go-No-Go commissions). Likewise, both Jonkman et al. (2003) and Casey et al. (1997) found significant decreases in commission errors on these tasks between age 9 and young adulthood (see also Jonkman, 2006; Klimkeit, Mattingley, Sheppard, Farrow, & Bradshaw, 2004). Cragg and Nation (2008) used a modified Go-No-Go task in which children had to depress a home key prior to pressing a target key. This modification allowed for partial commission errors (depressing of home key but not pressing target key in response to the no-go stimulus) in addition to traditional commission errors. In comparing 5- to 7-year-olds with 9- to 11-year-olds, only the partial commission measure was sensitive to developmental change, revealing that older children were able to inhibit a motor plan (releasing the home key and pressing the target key) at an earlier stage of execution than younger children. Johnstone et al. (2007) also found that the traditional no-go commission error was insensitive to change from ages 7 to 12. In contrast, they did find that performance on a Stop-Signal task, during which the child must inhibit a currently activated response, was sensitive to change across this age span. Thus, these two studies suggest that the stage of execution is a factor in inhibition difficulty: Terminating an already executed response appears to be more difficult than inhibiting a response that has yet to be executed or is in an earlier stage of execution.

In a computerized anti-saccade task (Fischer, Biscaldi, & Gezeck, 1997; Munoz, Broughton, Goldring, & Armstrong, 1998), children fixate on a central target. The target is turned off and a peripheral cue is turned on. Children are told not to look at the target but instead to look to the opposite side. Thus, any initial glance toward the cue is an inhibitory failure. Dramatic improvement in both reaction time and accuracy during the grade school years is followed by slower improvement during early adolescence. Similarly, Williams, Ponesse, Schachar, Logan, and Tannock (1999) found improvement up through age 12 on a "stop-signal reaction time" task, involving inhibition of a response (key press) to stimuli when a tone sounds. Moreover, Huizinga et al. (2006) found continued improvement in both reaction time and accuracy measures on the Stop-Signal task and Eriksen Flankers task until age 15 and on a Stroop-like task (inhibiting saying a color word in order to state its conflicting font color) until age 21. Finally, adults, more than adolescents, appeared aware of making an inhibition error as they momentarily slowed their response for the next trial in order to prevent further error (Hogan, Vargha-Khadem, Kirkham, & Baldeweg, 2005), which suggests the contributions of metacognitive development even after adolescence.

The fact that several studies have found improved performance beyond early childhood on ostensibly simple response inhibition tasks (e.g., anti-saccade task)—or at least on tasks (e.g., Go-No-Go task) simpler than conflict tasks—challenges the notion that performance on these tasks matures early on. For example, the computerized Go-No-Go task should be easier than Luria's hand game because it requires only response inhibition of a prepotent response rather than response inhibition followed by the execution of an alternative response. One explanation for this involves how task performance is measured. Computerized tasks contain multiple trials and measure reaction time very precisely (to the millisecond), thus increasing sensitivity to subtle changes. Alternatively, since many of these studies with older children have utilized computer-based tasks, perhaps some of the age-related improvements are related to computer-specific abilities (e.g., more efficient use of keyboard or mouse).

In summary, the first leap in attaining inhibition appears in the preschool years. By age 4, children show signs of successful performance on both simple (i.e., pure response inhibition) and complex inhibition tasks (i.e., response inhibition plus alternative response). By the same age children can operate on a bidimensional card by one dimension and then inhibit that to use the second dimension (i.e., successfully perform DCCS). Inhibition continues to improve, particularly from age 5 to 8 (Romine & Reynolds, 2005) and particularly for tasks that combine inhibition and WM (Carlson, 2005; Gerstadt et al., 1994), but also at later ages, especially on computerized tasks. Unlike the early improvements, these are unlikely to be fundamental changes in cognition (e.g., like preschoolers' acquisition of the rule-formation ability needed to perform the DCCS). Instead, refinements seem to involve quantitative improvements in accuracy, perhaps due to an increasing efficiency to override prepotent responses. Thus, it may be that inhibition tasks have varying sensitivities, with some being sensitive to the conceptual gains in early childhood and others being sensitive to the refinements in strength of the relevant cognitive skills or the generality of application in later childhood and even adolescence. These sensitivities seem to be determined by a number of factors including how performance is measured, the response modality, the strength of the response bias, the stage of response execution, and the degree of simultaneous WM demands imposed by the task.

Evidence from neuroscience. One method to examine the neural response underlying response inhibition is to measure the brain's electrical activity via electroencephalogram (EEG). Measuring during infancy, early childhood, and middle childhood, one longitudinal EEG study (Bell, Wolfe, & Adkins, 2007) reported qualitative change in brain activity underlying complex response inhibition—measured by WM and inhibitory control tasks. At 8 months of age, correct performance on the A-not-B task was associated with increased global cortical activity, whereas at age 4½, day-night performance was associated only with increased medial-frontal activity. By age 8, this activity became even more focused in the right frontal scalp regions during completion of the WCST. This shift from global to localized activity during task completion may signal the growing efficiency of the brain and the growing functionality of the PFC for complex response inhibition.

EEG studies with older children indicate continued localization of brain activity from middle childhood to adulthood. Looking closely at frontal activity, Jonkman (2006) found a linear increase in no-go P3 amplitude (a positive wave 300–500 ms after stimulus presentation) across development: Children aged 6–7 showed no P3 activity, children aged 9–10 showed limited P3 activity in frontal-central electrodes, and young adults showed broad P3 activity across frontal and frontal-central electrodes (see also Jonkman et al., 2003). P3 activity has been interpreted to index the allocation of attentional resources during stimulus engagement, with greater activity representing greater resource allocation (Polich, 1987). In contrast, the no-go N2 response (a negative wave 150–400 ms after stimulus presentation) decreased across the same age span, with the largest decrease in amplitude occurring between ages 6 and 10. The N2 response is thought to indicate conflict monitoring, needed when the prepotent response conflicts with the task-required response. The decrease in the N2 response may indicate that compensatory mechanisms are present in younger children and that the task induces less conflict with increasing age (Jonkman, 2006).

Similar findings come from Lamm et al. (2006) who reported decreases in frontal N2 amplitudes from ages 7 to 17 on no-go trials, which they attributed to increasing neural efficiency that may result from the regressive neural changes described above (e.g., synaptic pruning). As evidence that frontal N2 activity reflects conflict monitoring and inhibition, performance on tasks requiring conflict monitoring and inhibition (the Stroop task and Iowa Gambling Task) predicted decreases in frontal N2 amplitudes beyond that predicted by age. As further support, Johnstone et al. (2007) observed stronger frontal N2 activity in response to no-go stimuli than go stimuli. However, they found no change in the ability to inhibit no-go responses across the ages of 7–12. Moreover, what age-related changes in brain activity the authors did observe were found in nonfrontal brain regions—including decreases in central and parietal N2 amplitude—suggestive more of refinements in stimulus processing than in the inhibition response per se. All together, these EEG studies provide evidence that inhibition development is paralleled both by increases and decreases in neural activity, perhaps indicative of progressive and regressive neural change.

Researchers also have used neuroimaging assessments, such as fMRI, to document the increasing efficiency of the neural response underlying response inhibition. On the Go-No-Go task, Casey et al. (1997) observed no difference in the *location* of activation in the PFC between children ($M_{\text{age}} = 9.92$) and young adults but did measure *greater volume* of activation in children during the no-go condition, particularly within the dorsal and lateral PFC. Moreover, a longitudinal imaging study (Durston et al., 2006) reported that activation within the PFC only increased from ages 9 to 11 for specific prefrontal regions (ventral PFC) correlated with task performance. In contrast, activity within prefrontal regions uncorrelated with task performance (dorsolateral PFC) decreased with age. Similar to the explanation offered by Lamm et al. (2006), Casey et al. and Durston et al. (2006) suggested that the greater activation in children may correspond to inefficiency in the inhibition mechanism and that neural development is characterized by increased localization of activity to brain regions directly linked to the behavioral response and decreases in activity in supplementary brain regions.

One structural imaging technique, diffusion tensor imaging (DTI), measures the myelination of axons. Myelinated axons transmit signals more efficiently and rapidly than unmyelinated axons. Liston et al. (2006) measured myelination in participants aged 7–31, who also performed a Go-No-Go task and found that myelination of projections from the PFC to the striatum increased with age and correlated with no-go task performance. Importantly, myelination of corticospinal axons also increased with age but did not correlate with task performance. Thus, the increasing myelination of frontostriatal connections, in particular, across childhood and adolescence seems to underlie the maturation of response inhibition.

A synthesis of these neuroscience studies does not suggest a one-to-one correspondence between changes in brain activity and changes in task performance. Instead, task performance often changes subtly, if at all (e.g., Johnstone et al., 2007), whereas the pattern of neural activity may change dramatically. It seems that school-age children can successfully complete response inhibition tasks (with concurrent WM requirements or not) but, in doing so, enlist a more global pattern of activation than they will later on. With development comes localized and efficient activation in specific PFC regions (e.g., ventral PFC) pertinent to task completion. These dramatic changes in neural activity may translate into only subtle improvements in response inhibition, such as greater efficiency and less effort.

Developmental issues. Several developmental issues about inhibition need to be examined further. First, by what process does a child move from one level (e.g., simple inhibition of a response) to another level (e.g., the development of a more complex rule that controls two responses)? Does the former contribute to the development of the latter? Would examining the transition period yield clues to the qualitative and quantitative aspects of this change? Second, what is the form of the developmental trajectory from age 3 to adolescence? Is development linear? This question is difficult to answer because of the difficulty of finding appropriate tasks for a large age span. The dramatic improvement from ages 3 to 5 appears to be followed by less dramatic change from 5 to 8 and even less change after age 8 (although brain maturation continues). However, the tasks used with younger children likely have different inhibitory requirements than those used with older children. In a meta-analysis of EF studies from age 5 to adulthood, Romine and Reynolds (2005) found the greatest advancements in inhibition of prepotent responses from ages 5 to 8. A meta-analysis that includes younger children is greatly needed to clarify the rate of change from the preschool to grade school years.

Relevant to this apparent developmental trajectory is the problem of task impurity. Inhibition appears not to be a uniform construct. For example, interference control, cognitive inhibition, and motor inhibition may be distinct processes tapped by different tasks and develop at different rates across childhood (Nigg, 2000). Furthermore, classic tasks of inhibition utilize cognitive components in addition to inhibition. As already mentioned, many tasks also have significant WM requirements. For another example, performance on the Stroop task may depend not only on the ability to inhibit reading a color word in order to read its actual color but also on the child's level of reading automaticity (Leon-Carrion, García-Orza, & Pérez-Santamaría, 2004). As a result, performance, measured in terms of reading errors, does not improve in a linear fashion, but rather forms a quadratic relation: There is an initial increase in reading errors from ages 6 to 10, followed by a dramatic decrease in errors through age 17. This suggests that as word reading becomes more and more automatic from ages 6 to 10, inhibition of that process to say the color becomes more difficult, which negatively affects reading accuracy. Afterward, the inhibition mechanism needed may be mature enough to compensate for this reading automaticity. Thus, this developmental trajectory may have as much to do with developing reading automaticity as with developing inhibition. A similar careful analysis of other inhibition tasks might reveal similar complexities regarding the question: ''What develops?''

Adding further complexity, social factors likely influence inhibition performance. For example, there is evidence for a developmental regression in self-regulation in early adolescence (Anderson, 2002), particularly as evidenced by increased risky behavior during this time (Steinberg, 2007). One perspective suggests that the interaction of a mature socioemotional network (involving mainly limbic structures) and an immature EF-related control network within a context of increased peer pressure leads to adolescents' increased risk taking (Steinberg, 2007). This perspective suggests that outward regressions may occur not so much because there are actual regressions in inhibition per se but because exposure to emotionally laden and risky situations increases at this point in development when inhibition is still immature.

Summary. Regarding the first component in the Miyake et al. (2000) model, cognitive, behavioral, and brain assessments generally show rapid early improvements in inhibition followed by slower improvements through adolescence, along with greater brain localization throughout childhood and adolescence. Mechanisms of development may include brain maturation, increased ability to handle task complexity, increased ability to use rules, and emerging metacognition.

Working Memory

Like inhibition, WM research has been complicated by various definitions of the construct, as well as (and perhaps resulting in) the use of differing assessment tasks. In general, WM involves the ability to maintain and manipulate information over brief periods of time without reliance on external aids or cues (Alloway, Gathercole, & Pickering, 2006; Goldman-Rakic, 1987; Huizinga et al., 2006). Neuroimaging research suggests that WM tasks vary by how much the task elicits PFC activity; consequently, researchers suggest that WM tasks vary in the degree to which they require ''executive control'' (Luciana et al., 2005). That is, more complicated WM tasks that require the maintenance and manipulation of information in order to direct behavior toward future goals (e.g., backward digit span, delayed-response tasks, self-ordered searches) ostensibly rely on more executive involvement (and consequently more PFC activity; D'Esposito & Postle, 1999) than simpler WM tasks that require only the maintenance of information (e.g., forward digit span). Accordingly, the rate and form of WM development will hinge upon the degree to which a task requires executive processes.

Gathercole, Pickering, Ambridge, and Wearing (2004) invoked the classic WM model of Baddeley and Hitch (1974) to distinguish between executive WM tasks and online storage tasks. According to Gathercole et al., executive WM requires that either the verbal storage system (i.e., the phonological loop) or the visuospatial storage system (i.e., visuospatial sketchpad) work in concert with a coordinating central executive. Simple WM tasks require little input from the central executive but rely solely on either the phonological loop (e.g., forward digit recall) or visuospatial sketchpad (e.g., visual pattern recall). Complex tasks (e.g., backward digit recall), on the other hand, may require that multiple WM tasks be performed concurrently, and therefore the central executive must coordinate those processes. This tripartite model was supported by a CFA of children aged 6–15 on a battery of verbal WM, visuospatial WM, and executive WM tasks, which suggests the differentiation of the WM subsystems by early grade school.

Age differences. A variety of tasks document improvement in WM during the preschool years (see Garon et al., 2008). Gathercole et al. (2004)

reported that by age 6, the executive component of WM is sufficiently developed to be used during complex tasks that require coordination of WM subcomponents. In addition, the same researchers found that simple and complex WM tasks had similar developmental trajectories—a linear increase from ages 4 to 14 and a leveling off between ages 14 and 15 across nearly all tasks examined. Luciana et al. (2005), drawing on a battery of nonverbal tasks, found that the developmental course of WM depends on the complexity and, thus, the executive demands, of the task, with less demanding tasks being mastered earlier in development. Their battery of nonverbal tasks ranged from a nonverbal face recognition task (lowest executive demand) to a spatial self-ordered search (highest executive demand). The former simply required the child to maintain a facial representation over a delay in order to discriminate a previously viewed face from a novel one, and performance was unchanged between ages 9 and 20. The latter task required the child to search varying locations on a computer screen for hidden tokens, to remember locations where a token was found, and to strategically explore other locations, and performance continued to improve until age 16.

Extending the work of Luciana et al. (2005), Conklin et al. (2007) used a battery of verbal and spatial WM tasks across the ages of 9–17. Across age, children tended to perform better on the spatial versus verbal WM tasks, even though the tasks were thought to tap similar cognitive processes (e.g., strategic self-organization). Still, the developmental trajectories were similar for verbal and visuo-spatial WM tasks, and instead, differed based on task complexity. In agreement with the conclusions of Luciana et al., Conklin et al. suggest that the age of mastery depends more on the degree of *processing* (with more complex tasks requiring a greater degree of processing) rather than the *content* to be processed (e.g., verbal vs. visuospatial material).

One problem, although, with this use of different tasks to manipulate the executive demands on WM is that it is difficult to ensure that non-EF processes are equivalent across tasks and that they do not influence age differences in performance. Luciana and Nelson (1998) addressed this important issue by employing only a self-ordered search task, which varied over trials in the executive demands, based on the number of locations (2–8) the child may search for tokens. By increasing the number of search locations, greater demands are placed on the executive components of WM to search strategically and to avoid previously searched locations by continually updating WM. Similar to the findings of Luciana et al. (2005), for the least demanding condition, performance was equivalent among children aged 4–8, adolescents, and young adults. However, as the number of search locations increased, age differences emerged. For three locations, performance maturity was reached at age 6, for four locations, maturity was not reached until adolescence, and for six and eight locations, improvements continued until adulthood. Thus, the development of executive WM occurs gradually with continued refinement through adolescence, especially for tasks that require the maintenance and manipulation of multiple items.

Evidence from neuroscience. In accord with the behavioral results, fMRI evidence points to a protracted developmental course leading to localized activity within the PFC during WM functioning. Kwon, Reiss, and Menon (2002) reported a quantitative linear increase in activity within a frontoparietal network, including ventral and dorsal regions of the PFC, from ages 7 to 22 while performing a visuospatial WM task (*n*-back task). The authors note that the increased activity within right-lateralized dorsal PFC likely subserves the maturation of visuospatial attention and executive processes, whereas the increased activity within a left-lateralized frontoparietal network subserves the maturation of a phonological rehearsal system. Increases in this neural activity were related more to age than to task performance (accuracy and RT). Thus, with a dramatic and prolonged increase in specialization of the WM neural circuitry through childhood and adolescence comes only limited overt task improvement, especially during adolescence.

Scherf, Sweeney, and Luna (2006) reported both qualitative changes (location of activation) and quantitative changes (amount of activation) in the neural response underlying visuospatial WM from childhood ($M_{\text{age}} = 11.2$) through adulthood ($M_{\text{age}} = 29.5$). During childhood, activation occurred in qualitatively different premotor regions and also in the lateral cerebellum, which was absent in later development. Also during childhood, there was quantitatively greater activity in ventromedial regions, including the thalamus and basal ganglia. Adolescence ($M_{\text{age}} = 15.7$) brought a shift in activity to frontal regions, including the right dorsolateral PFC. Finally, from adolescence to adulthood, activity became more localized and lateralized as left dorsolateral PFC activation increased and right dorsolateral PFC activation decreased. Moreover, activity increased substantially in the anterior cingulate (described as qualitative change by the authors). The end result of these changes (quantitative and qualitative, progressive and regressive) from childhood to adulthood is a functionally specialized visuospatial WM neural network (see Klingberg, Forssberg, & Westerberg, 2002, for similar changes from ages 9 to 18 on a visuospatial WM task).

Increased WM also correlates with structural neural indices, such as the maturation of white matter (i.e., the myelination of neuronal axons), measured by DTI. Nagy, Westerberg, and Klingberg (2004) reported that the development of visuospatial WM from ages 8 to 18 correlated with myelination in regions primarily of the frontal lobe close to the parietal lobe (superior and inferior left frontal lobe), whereas the development of reading ability correlated with myelination in the left temporal lobe. Thus, during late childhood and adolescence, the maturation of specific cognitive functions is linked to the maturation of specific neural circuits, rather than to global brain maturation.

Developmental issues. One developmental issue concerns the developmental relation between WM and inhibition. It seems that many inhibitory tasks, particularly complex ones, also place demands on WM (Bell et al., 2007; Garon et al., 2008; Simpson & Riggs, 2005), and the combination of the two within a single task poses significant difficulty for young children (e.g., Carlson, 2005). For example, in the day-night task the child must maintain the rule in WM. However, research also suggests their independence. If the inhibitory component is eliminated on this task, the difference between 3.5- and 5-year-olds nearly disappears (Simpson & Riggs, 2005), which suggests that it is inhibition, not WM, that causes the age difference. (It is also possible that eliminating the WM component also would reduce the age differences, which would suggest that the interaction of the two components is important.) Similar outcomes were found with a Stroop-like task, a CPT task, and a start–stop task (Beveridge, Jarrold, & Pettit, 2002), as well as the DCCS (Zelazo et al., 2003). Thus, relevant to the Miyake et al. (2000) model, it appears that WM and inhibition are largely separate constructs (for a counterargument, see Bell et al., 2007; Davidson et al., 2006). That said, many tasks described as either WM or inhibition tasks likely place demands on both types of processes (e.g., the day-night task), and therefore, it is difficult to obtain a pure measure of one or the other.

Summary. Performance on complex WM tasks (i.e., those tasks requiring a greater degree of processing such as the maintenance and manipulation of information) improves at least through adolescence. Like the development of the neural circuitry subserving response inhibition, the development of the WM circuitry involves progressive and regressive changes, resulting in a localized pattern of activity within a frontoparietal network, including the DL-PFC. Unlike the trajectory of inhibition development that shows large improvements during the preschool years followed by more modest, linear improvements through adolescence, most of the evidence suggests that the trajectory of WM development is linear from preschool through adolescence.

Shifting

The third core EF is the ability to shift between mental states, rule sets, or tasks (Miyake et al., 2000). There appears to be substantial need for inhibition and WM processes for shifting. Reminiscent of the cognitive processes associated with inhibition tasks (e.g., DCCS), Miyake et al. (2000) suggest that shifting may "involve the ability to perform a new operation in the face of proactive interference or negative priming" (p. 56). It would seem, then, that the ability to inhibit previously activated mental sets would be important for successful shifting and that perseverative errors (i.e., continued responding based on the previous mental set) would indicate shifting failures (Anderson, 2002). The typical distinction between tasks deemed "inhibition tasks" and those deemed "shifting tasks" is that the latter typically rely on switching between two or more mental sets—with each set possibly containing several task rules—rather than the inhibition of a single response (Crone, Somsen, Zanolie, & Van der Molen, 2006). Moreover, in tasks of inhibition, the rules are usually explicitly expressed rather than implied through either negative or positive feedback. Thus, the DCCS with its explicit indication of set change is often categorized as an inhibition task (but see Garon et al., 2008, who classify the DCCS as a shifting task). Shifting tasks also place demands on WM by requiring the maintenance and updating of that mental set based on feedback.

Age differences. The ability to shift improves with age (Anderson, 2002; Cepeda, Kramer, & Gonzales de Sather, 2001; Crone, 2007; Crone et al., 2006; Garon et al., 2008; Somsen, 2007). Preschoolers, aged 3–4, can successfully shift between two simple response sets in which the rules are placed in a story context (Hughes, 1998) or when demands on inhibition are reduced (Rennie, Bull, &

Diamond, 2004). For example, in a simplified version of the WCST (Hughes, 1998), preschoolers can determine what a teddy bear's favorite shape is, based on feedback, and then after a set shift they can decide what a second teddy bear's favorite color is, based on differing feedback.

As previously mentioned, Senn et al. (2004) reported that whereas inhibition and WM were interrelated and predicted complex task performance (i.e., TOH), shifting was unrelated to inhibition, WM, or TOH performance in preschoolers. Accordingly, the authors suggest that shifting may not be differentiated from WM and inhibition—and therefore, is less developed—at this age. This is sensible given that inhibition and WM processes seem to be prerequisite processes for successful shifting. As Garon et al. (2008) noted, before children can successfully shift between response sets, they must be able to maintain a response set in WM and then be able to inhibit the activation of a response set in order to activate an alternative one.

More complex tasks show further development in older children and adolescents. Luciana and Nelson (1998) utilized a set-shifting task that progressed through nine stages of increasing difficulty and complexity (the intradimensional–extradimensional set-shifting task from the CANTAB). This is a fruitful strategy as it shows exactly how complex a set children can handle at each age, thus permitting comparisons across a wide age range. This task required children to respond correctly, based on previous feedback, to either lines or shapes presented on a computer. Children had to attend to feedback, infer the correct rule at that moment, and respond accordingly. At set points, reinforcement switched such that the correct response (e.g., shapes) switched to the opposite of what was previously correct (e.g., lines). The main improvement occurred from ages 5 to 6, at Stage 7, in which the rule did not switch (i.e., between lines and shapes), but the examples of lines and shapes did change. For successful completion of this stage, children needed to utilize feedback from previous stages to shift their response to new examples of either lines or shapes. With increasing age up through young adulthood, there was a steady increase in the proportion of subjects who completed all nine stages of the task, indicating that shifting ability continues to improve over many years.

Huizinga et al. (2006) investigated set shifting on three computerized tasks in which a cue signaled to which dimension the child should respond. Sporadically, the cue would switch, indicating a set shift. ''Shift cost'' was the difference in response time between shift trials and nonshift trials. The shift cost for the 7- and 11-year-olds was significantly greater than for the 15-year-olds, who did not differ from the young adults ($M_{\text{age}} = 20.8$). Thus, shifting reached adult-like levels around age 15. Similarly, Davidson et al. (2006) found improvement from age 4 through adolescence. Interestingly, they found different developmental trajectories for the switch cost for accuracy versus reaction time. Whereas the shift cost to accuracy diminished through early adolescence, the switch cost to reaction time increased until adulthood. This speed–accuracy trade-off indicates that with increasing age, participants were more likely to slow down their responses on shift trials to ensure that they were responding accurately. Thus, improved metacognition—knowing that slowing helps performance and being able to detect when it is advantageous to do so—may be one mechanism of developing accurate set shifting. This design, examining developmental curves on two or more measures, is a model for how future research could tease apart aspects of an EF component and tell a more nuanced developmental story.

Evidence from neuroscience. In further support of the role of metacognition, especially monitoring and changing one's own performance, Crone et al. (2006) measured heart rate changes during a task shifting paradigm, in which the child ''opened'' doors on a computer screen in order to help a computerized donkey find its way home. Heart rate slowing following negative feedback (indicated by a negative sign after opening an incorrect door) would indicate a realization of an error and the evaluation of the current set rules. For ages 8–18, heart rate slowed to a similar degree following the unexpected feedback that occurs immediately after a task shift. The difference between the age groups occurred only in errors that continued after receiving feedback for a task shift. Following such an error, the 8- to 10-year-olds did not show heart rate slowing as much as the 12- to 14-year-olds or the 16- to 18-year-olds. Thus, although younger children could detect a task shift as well as older ones, they did not detect performance errors after the shift as well. Somsen (2007) reported that on a computerized WCST an increase in attention to feedback about errors predicted performance in adolescents, but not younger children, which again supports the role of metacognition, particularly being able to use feedback to change one's behavior.

fMRI analyses implicate neural activity within multiple regions of the PFC and elsewhere as shifting develops. Rubia et al. (2006) reported increased activation in inferior frontal, parietal, and anterior cingulate regions, but decreased DL-PFC activation across adolescence during shifting. They proposed that the increased activity in the anterior cingulate cortex (ACC) reflects the maturation of conflict monitoring processes, whereas the increased DL-PFC activation in younger participants reflects compensatory neural activity—quite similar to the explanation offered by Casey et al. (1997) regarding Go-No-Go performance.

Also focusing on conflict monitoring, Crone (2007) suggested that other regions may underlie the growing ability to monitor and change one's performance. During development, adult levels of processing feedback about performance on a shift task are reached first for the medial PFC (important for violations of processing expectations), and then for the left dorsal PFC (important for hypothesis testing and seeing the need for adjustment of behavior). The first development occurs between ages 8 and 10 and adolescence and the second between adolescence and adulthood. Thus, because cognitive shifting requires the child to switch between multiple response sets based on feedback, neural networks involving the ACC and regions of the PFC that are responsible for monitoring and detecting conflict (e.g., performing a response and receiving negative feedback) seem to be critical to successful shifting.

Developmental issues. A useful approach for pinpointing exactly *what* changes with age on a shifting task is to break such a task down into component processes and examine neural correlates of age changes in these processes. A recent interesting study (Morton, Bosma, & Ansari, 2009) examined separately two processes in the DCCS task: (a) rule switching (e.g., switching from color- or shape-based sorting) and (b) detection and resolution of conflict when stimuli can legitimately be sorted in two ways (color or shape). Rule switching showed fMRI activity in the lateral PFC and posterior parietal cortex in both children and adults. Most interesting, however, was an interaction of rule switching and age in these regions. Rule switching modulated activity in the left posterior parietal cortex and right middle frontal gyrus in adults but not in children. Thus, the networks involved in switching presented a qualitative developmental change from childhood to adulthood. Although the age-related results were less clear for conflict processing, they showed that conflict processing and rule switching are separable processes that, when considered separately, can give a more fine-grained analysis of age-related neural and behavioral changes on the DCCS task.

Age-related improvements in shifting also occur through the development of processes other than shifting per se. For example, the ability to generalize a rule set to a novel set of stimuli facilitates shifting performance (Luciana & Nelson, 1998). The abilities to maintain the new rule set and to detect performance errors after a successful shift also are important (Crone et al., 2006). Finally, the development of metacognitive strategies, such as slowing down responses to preserve a high level of accuracy, enhances accurate shifting (Crone et al., 2006; Davidson et al., 2006).

Summary. The ability to successfully shift between task sets follows a protracted development through adolescence. It appears that preschool-aged children can handle shifts between simple task sets and later can handle unexpected shifts between increasingly complex task sets. Both behavioral and physiological measures indicate that during adolescence, monitoring of one's errors is evident, and by middle adolescence, task switching on these complex shift paradigms typically reaches adult-like levels. Because of greater need for multiple cognitive processes, mature shifting likely involves a network of activity in many PFC regions.

Conclusions About Development and Directions for Future Research

Developmental Trajectories

It is clear that previous reviews of EF in children, mainly focused on preschoolers, leave out much of the story of the development of EF and limit the search for sequences and mechanisms of development. There is substantial further development in all components after age 5, and even through adolescence (see Best et al., 2009). Including broader age ranges provides information about developmental trajectories. Results are inconsistent, but inhibition appears to show particularly striking improvement during the preschool years and less change later on. WM shows more gradual linear improvement throughout development, as does shifting. These different trajectories provide support for the Miyake et al. (2000) position that the three components are somewhat diverse. However, the differing trajectories extend the Miyake et al. model by suggesting that the degree of unity or diversity of EF varies from age to age.

The evidence suggests both quantitative and qualitative EF development. Much of the change appears to be quantitative and gradual, although the change may be more rapid in the early years. In many relevant brain regions, activity decreases with age, perhaps reflecting the growing efficiency of the neural response. Some change appears to be qualitative, suggesting changes in brain organization as the site of brain activity shifts during development (e.g., Scherf et al., 2006). In other regions, activity seems to increase—for example, in the ventral PFC during response inhibition and in the DL-PFC during WM. As Olson and Luciana (2008) note, the discrepant behavioral trajectories along with this segregation of activity tentatively suggest that different regions of the PFC support different EFs. Thus, regional differences in the course of neural development may be responsible for different developmental trajectories of response inhibition, WM, and shifting. The emergence of metacognition may also bring qualitative change when children learn to use feedback about errors to change their approach to the task.

It is important to note that despite evidence for the functional differentiation of the PFC, there also seems to be activation of common regions during the completion of distinct EF tasks. This may in part be due to EF task impurity—notably the fact that it is difficult to tease apart WM and inhibitory processes (Roberts & Pennington, 1996) and that shifting likely builds on WM and inhibitory processes (Garon et al., 2008). Additionally, it may indicate the common processes that underlie the various EF components, that is, the "unity" aspect of the "unity and diversity" of EF (Miyake et al., 2000). Exactly how EF is instantiated in the brain, including to what degree the PFC is functionally differentiated, continues to be a debated issue (Olson & Luciana, 2008).

Several task-related factors also influence the observed developmental trajectory of a latent EF component. One is the degree of task complexity, with better success expected on simpler tasks. Task complexity can be manipulated in several ways, but notably by increasing the degree of response prepotency in inhibition tasks (Diamond & Taylor, 1996) or by increasing the degree of "working" with information in WM tasks (Luciana et al., 2005). Thus, a simple response inhibition task should be easier than the Stroop task, and a WM task that requires online storage should be easier than one that requires information manipulation. A second is how performance is measured (e.g., partial vs. full commission error on the Go-No-Go task; Cragg & Nation, 2008). A third is the response modality (e.g., bodily vs. verbal response; Diamond & Taylor, 1996). Thus, researchers need to consider carefully how these task factors may shape the developmental trajectory of constructs ostensibly measured by such tasks. Moreover, the influence of these task factors suggests caution in drawing strong conclusions about the development of EF.

Mechanisms of Development

Research needs to move beyond a focus on description—the ages at which the EF components emerge, show rapid development, and reach maturity—and address mechanisms of development. How do children move from early to later levels of competence within an EF component, for example, inhibition? Does the early phase of development of one component facilitate the development of other components? The developmental relations between components of EF could be examined by research designs that include assessments of several components of EF together in the same study, at different ages. The comparison of trajectories of several EF components can suggest mechanisms of development. For example, the early rapid improvement in inhibition may contribute to the later developments of shifting and planning.

Promising designs. Several designs used by studies reviewed here seem particularly promising for examining mechanisms of development within or between components: (a) Use meta-analyses (Romine & Reynolds, 2005) to examine the effects of moderating variables at different ages by including a larger age range. (b) Compare the developmental trajectories for two or more aspects of performance (e.g., speed and accuracy, Davidson et al., 2006; Baker, Segalowitz, & Ferlisi, 2001; number of moves, amount of planning time prior to making the first move, and the proportion of perfect solutions on the TOL task, Huizinga et al., 2006) for clues as to whether one aspect influences another. (c) Look for correlations between a measure of neural activity and EF performance (e.g., Morton et al., 2009). Brain maturation could permit, and thus serve as a developmental mechanism for, more advanced EF behavior, or the latter behaviors could cause changes in neural networks.

Another promising, yet rarely used, approach is to focus on the transition phase from one developmental level to the next. An example is the change from the simple rule necessary for inhibition on simple conflict tasks to the more complex rules necessary for inhibition on the DCCS task. The microgenetic method is particularly useful in this regard. In this method, children have multiple trials on the same task or similar tasks, typically in several sessions over several weeks, and trial-to-trial changes are examined. Using this method, McNamara, DeLucca, and Berg (2007) tracked detailed change in the type of strategy used with increased experience on the TOL task. Potentially a microgenetic design could show that rapid change in one component is subsequently followed by rapid change in another component, suggesting a possible causal relation.

Microgenetic studies could be particularly useful for examining what happens at the point of shifting on shift tasks, given that several studies have observed changes that suggest metacognitive processes at work on the trials after the shift (e.g., Crone, 2007; Crone et al., 2006). In a task similar to shift tasks (DeMarie-Dreblow & Miller, 1988) when young children have to shift from one category (e.g., animals) to another category (household items) on a selective memory task, their previously effective strategy of attending to only relevant items transferred successfully to the new category but temporarily became ineffective at facilitating recall of the relevant items in this newly relevant category. Such fine-grained assessments of microgenetic changes in behavior would be particularly powerful if combined with neuroimaging assessments that track changes in brain activity at the point of behavior change.

Training studies also are useful for examining possible mechanisms of development. These can look at short-term change by (a) training one EF component and then assessing any immediate changes in other components, or (b) providing particular experiences, such as metacognitive instruction, and observing any facilitation of EF.

Training studies also can examine mechanisms over longer periods of time. The most powerful assessments of developmental mechanisms would track changes in both cognitive performance and brain organization, thus providing a multilevel assessment of influences. Such studies are rare. One such line of investigation showed both improved EFs and change in fMRI patterns of brain activity associated with EF after a 3-month after-school high-intensity exercise program for ages 7–11 (Davis et al., 2007, in press). In comparison to a control group, the exercise group had increased bilateral PFC activity and reduced bilateral posterior parietal cortex activity during an inhibition task. Another study (Rueda, Rothbart, McCandliss, Saccomanno, & Posner, 2005) reported evidence that 1 week of training on a computerized program centered on executive attention led to a more mature EEG response to an inhibition task (modified flanker task) and to small, although often insignificant, behavioral improvements on the inhibition task and on a generalized intelligence test.

Finally, a powerful approach to identifying developmental mechanisms underlying changes in EF would be to study whether the cognitive, biological, and social correlates of EF change from one age to another (see Best et al., 2009, for a discussion of the social correlates of EF). This is particularly important because different processes may contribute to the development of EF at different ages.

Developmental sequences. Another good starting point to search for possible mechanisms of development is to examine developmental sequences underlying the emergence of each EF component (for a description of types of developmental sequences, see Flavell, 1972). Observed developmental sequences can suggest how early cognitive skills might be related to later ones. For example, does the development of a more advanced inhibitory ability *supplement* earlier inhibitory ability (i.e., an "addition" sequence), for example, by strengthening it, adding the ability to select an alternative response to the ability to inhibit the prepotent response, or adding metacognitive skills? Or does a more advanced, integrated inhibition skill *replace* earlier forms of inhibition, as suggested by the evidence of brain reorganization (e.g., the loss of compensatory activation with development) correlated with more advanced inhibition? In this qualitative change, the old brain organization associated with simple inhibition may no longer exist. The microgenetic design mentioned above could address supplementing versus replacing by showing whether Skill A continues to be used even after Skill B emerges.

A similar analysis of sequences and possible mechanisms could also address how the various EF components are related developmentally. That is, some EF components may facilitate the development of other EF components. For example, as WM and inhibition seem to develop ahead of shifting (Davidson et al., 2006), perhaps a certain level of WM and inhibition has to be developed before children can use them toward the development of shifting behaviors (Garon et al., 2008). Two EF components may even be mutually facilitative, as each bootstraps the development of the other in a back-and-forth fashion. Garon et al. (2008) suggested that the emergence of the three components in the first 3 years of life may be followed by an integrative period in which they become coordinated. In short, a greater emphasis on detecting possible developmental sequences will allow for a clearer and more detailed understanding of the developmental trajectories of EF components as well as the developmental relations between those components. Finally, attention to sequences can clarify some of the differences among theories of EF development in how conflicting representations are resolved. For example, in Zelazo's CCC theory (Zelazo et al., 2003), two rules are integrated to produce a new overarching rule system. In contrast, in Munakata's (2001) theory, latent representations are maintained, even after active representations strengthen and override latent ones.

Two articles have attempted to extract developmental sequences. Anderson (2002) inferred the following sequence of EF components from an integrative review: attentional control (e.g., inhibition), information processing (e.g., processing speed), cognitive flexibility (e.g., switching), and goal setting. Romine and Reynolds (2005) inferred sequences from the age at which performance leveled off, based on a meta-analysis of ages 5–22 and average effect sizes of age-related change in performance. They found the following sequence: inhibition of perseveration, set maintenance, design fluency, planning, and verbal fluency.

One design for detecting sequences, rarely used in this research area, is to give children slightly different versions of the same task (to try to equate task demands, such as verbal demands and content area), with each task assessing a different component of EF (see Wellman & Liu, 2004, for the successful use of this design for assessing the acquisition sequence for theory-of-mind tasks). If task demands, other than the EF component of interest, are in fact equated, the mean performance on each version or the percent of children who pass each version suggests the order in which the components of EF are acquired. Also, a scalogram analysis could examine how many children pass all of the hypothesized easier versions of the task before a hypothesized more difficult task. That is, if the hypothesized ordering of component tasks from easiest to hardest is A, B, C, D, then the outcome of interest is how many children passed A, B, and C, but not D; A and B but not C and D; and A but not B, C, and D.

Carlson (2005) applied this method in a large sample aged 2–5 to determine the probability of passing common EF tasks at each age. Although the ordering of specific tasks varied from age to age, inhibition tasks routinely were passed earlier than WM tasks and the very hardest tasks consistently involved both inhibition and WM demands (e.g., reverse categorization at age 2, DCCS at age 3, backward digit span at ages 3 and 4, advanced DCCS at ages 5–6).

Finally, longitudinal studies obviously are ideal to detect sequences, but few exist. Several longitudinal studies have examined the TOH or TOL task, with a focus on developmental sequences in strategy use (McNamara et al., 2007), and family, cognitive, school achievement, and social adjustment correlates (Friedman et al., 2007; Jacobson & Pianta, 2007). On inhibitory tasks, one striking sequence identified is that performance on a delay of gratification task at age 4 predicts, and thus may be a developmental precursor for, performance on inhibitory tasks such as the Go-No-Go task at age 18 (Eigsti et al., 2006). In a longitudinal study from ages 2 to 4 (Hughes & Ensor, 2007), EF (an aggregate of inhibition, WM, and shifting tasks) improved with age and showed stable individual differences, indicating the predictive ability of early EF for later EF.

This review suggests several influences on children's level of performance on EF assessments that should be considered when examining sequences. One complication in identifying sequences is that estimates of performance, and thus developmental trajectories, may vary, depending on what aspect of performance is scored and how it is scored (e.g., Baker et al., 2001; Huizinga et al., 2006). Moreover, the apparent developmental order of two aspects (A then B) of EF actually could be due to the greater performance demands of B. Reducing the demands of B would reverse the sequence. For this reason the design suggested above, with different versions of the same task, ideally would use similar levels of task difficulty. These measurement issues obviously become even more challenging when assessing the sequence of a task requiring one EF component and a task requiring two components.

Mechanisms identified. The studies reviewed here suggest several likely developmental mechanisms (biological and environmental) of EF development for the focus of future research. Consistent with most developmental EF theories, the assessment of brain activity is important because it provides clues about how developing EFs become organized, as seen in changes in neural networks and increased localization. Such research is well underway, although this research focuses on inhibition and WM, and rarely shifting. One influential developmental model (Posner & Rothbart, 2007) proposes that the development of the anterior attention system—the executive attention network—during preschool is important for regulating other brain networks.

Large neural and behavioral changes in the components during the preschool years are followed by more gradual, fine-grained improvements later. However, establishing *specific* links between brain changes and changes in behavior has proven to be more difficult. Also, distinguishing individual performance differences in brain activity from maturational differences continues to challenge neuroimaging researchers (Thomas & Tseng, 2008). One promising approach is to include several brain and behavioral measures and examine which ones change from one age to another and which do not. For example, LaVallee, Muenke, Robertson, and Watamura (2007) compared EEG responses, reaction time, number of gaze shifts, and accuracy on a modified Stroop task (e.g., see a boy, hear the word "girl") in 3- versus 4-year-olds. Another promising approach is one (Morton et al., 2009) in which age differences in neural correlates of component processes (shifting vs. processing of conflict) were examined separately.

Two points should be made about brain-based changes as possible mechanisms. First, any change in brain function could be either a cause (i.e., neural maturation provides a mechanism of development) or an effect (i.e., EF behaviors lead to brain changes) or both. Second, cognitive neuroscience work would contribute more to the existing behavioral literature if it were tied to theoretical developmental issues such as quantitative versus qualitative change, degree of generalization of new EF skills, and domain-specific versus domain-general EF skills.

As for experiential-based mechanisms of EF development, several studies reviewed (e.g., Crone, 2007; Crone et al., 2006; Davidson et al., 2006; Hogan et al., 2005; Somsen, 2007) suggest that metacognition may play an important role during the school-age years and adolescence. Examples are an awareness of inhibition failures and the subsequent adjustments in response to avoid future errors, as well as slowing one's response in order to ensure high accuracy on a switching task. Current developmental EF theories, because they are based mainly on development in the first 5 years of life, are limited in this respect. Post-preschool detection of success or failure of one's current rule (Zelazo), latent representation (Munakata), mental set or prepotent behavior (Diamond), or focus of attention (Posner & Rothbart) may be important metacognitive developments that would extend these theories based on preschoolers to older children. The relevant aspects of metacognition may vary from one component to another. For example, it seems likely that knowing to slow down is particularly important in theories that emphasize inhibition, whereas detecting errors and considering alternative responses may be particularly important in theories emphasizing shifting.

Several other suspected contributors to EF include practice (e.g., McNamara et al., 2007), intense motor activity (Bell et al., 2007; Campbell, Eaton, & McKeen, 2002; Davis et al., 2007), language (Bell et al., 2007; for preschoolers only; Kray, Eber, & Lindenberger, 2004; Wolfe & Bell, 2004), bilingualism (Carlson & Meltzoff, 2008), maternal education and parenting (Friedman et al., 2007), and theory of mind (Hughes & Ensor, 2007; Perner & Lang, 2000)—understanding that mental states exist and affect behavior. Moreover, cultural differences, such as the earlier acquisition of EF in Chinese than U.S. children (e.g., Sabbagh et al., 2006), suggest that cultural values, perhaps as expressed in practices at school, may affect the development of EF.

Conclusions

Unlike previous reviews focused on preschoolers' EF, this review focused on EF across a much larger age span. This perspective permitted an examination of EF in light of central developmental issues such as the form of developmental trajectories, sequences of acquisition within EF development, qualitative and quantitative change, and developmental mechanisms at both behavioral and neural levels. Based on this framework of developmental issues, the key components of needed future research include: (a) use of a wide age range and comparable tasks to reveal the form of developmental trajectories of each EF component, (b) examination of several EF components so that relations among components can be examined, and (c) assessment of possible mechanisms of development. Such designs would move EF research from its current state—strong theoretical and empirical work on preschoolers, scattered nonintegrated work on older children, and emphasis on description of age differences—to a truly developmental account. This account would provide a developmental theoretical focus to cognitive neuroscience studies of children's EF. In turn, a more theoretically based developmental cognitive neuroscience would provide greater constraints on developmental issues and theories of EF than we have now.

Young Children Selectively Avoid Helping People With Harmful Intentions

Amrisha Vaish, Malinda Carpenter, and Michael Tomasello
Max Planck Institute for Evolutionary Anthropology

Two studies investigated whether young children are selectively prosocial toward others, based on the others' moral behaviors. In Study 1 ($N = 54$), 3-year-olds watched 1 adult (the actor) harming or helping another adult. Children subsequently helped the harmful actor less often than a third (previously neutral) adult, but helped the helpful and neutral adults equally often. In Study 2 ($N = 36$), 3-year-olds helped an actor who intended but failed to harm another adult less often than a neutral adult, but helped an accidentally harmful and a neutral adult equally often. Children's prosocial behavior was thus mediated by the intentions behind the actor's moral behavior, irrespective of outcome. Children thus selectively avoid helping those who cause—or even intend to cause—others harm.

Humans are not equally prosocial toward all individuals. Instead, we select the beneficiaries of our prosocial acts from among multiple potential beneficiaries. One crucial criterion for this selection is the beneficiary's helpful or harmful behavior: We help and affiliate with helpful individuals and shun or punish harmful individuals (e.g., Fehr & Gächter, 2002; Krebs, 2008). To date, almost no work has examined whether children make such selections. We do know that infants' social preferences for nonhuman agents are determined by those agents' helping or hindering behaviors (Hamlin, Wynn, & Bloom, 2007) and that children begin helping others early in life (Warneken & Tomasello, 2006, 2007), but relations between the two have not yet been assessed. Later, in the preschool years, children's abstract moral reasoning about story characters is related to their everyday prosocial behavior (Eisenberg-Berg & Hand, 1979; Janssens & Dekoviç, 1997). In one particularly relevant study, Olson and Spelke (2008) asked 3.5-year-olds to help a protagonist doll decide how to allocate resources to other dolls. Children allocated more of the protagonist doll's resources to a doll who was generous to the protagonist doll (direct reciprocity) or generous to a different doll (indirect reciprocity) than to a nongenerous doll, thus demonstrating some appreciation of direct and indirect reciprocity.

Olson and Spelke's (2008) study could also be interpreted as showing that young children consider others' moral behaviors when deciding whom to share with. However, sophisticated moral judgments take into account several factors, including not only the consequences of but also the intentions behind a behavior (see Cushman, 2008; Piaget, 1932/1997; Turiel, 2006; Turiel, Killen, & Helwig, 1987; Weiner & Peter, 1973). Thus, to show that children's prosocial behavior is mediated by others' moral behavior, one needs to show that the prosocial behavior is mediated not only by the outcomes of but also the intentions behind others' actions. In the present work, we assessed whether young children show differential prosocial behavior toward agents who vary in the helpful or harmful intentions underlying their behavior.

A secondary issue, also raised by Olson and Spelke (2008), is that children's responses on behalf of others (the protagonist doll in their study) may not correspond to children's responses when they themselves must decide whom to share with or help. Our first study thus tested whether children respond differentially to others' harmful or helpful behaviors even when they themselves are the ones sharing or helping. The primary question of the second study was whether intentionality mediates

children's judgments of others as worthy recipients of prosocial acts. Note that in both studies, children witnessed but were not the recipients of the harmful or helpful behaviors. Using such third-party interactions circumvents ethical issues and ensures that children's subsequent actions are responses to the actor's behavior rather than a result of their own emotional responses to being helped or harmed (see Olson & Spelke, 2008).

The general procedure of both studies was as follows: In a between-subjects design, after warming up with three adults, the children viewed four familiarization trials during which one adult (the actor) behaved in a condition-specific way (e.g., harmfully or helpfully) toward another adult (the recipient). The four familiarization trials were followed by one helping test in which children were presented with a forced choice between helping the actor or the third (familiar but neutral) adult. The dependent measure in both studies was thus instrumental helping, which is relatively easy to elicit without explicit verbal instructions (Warneken & Tomasello, 2006, 2007). A forced choice was included because young children are highly motivated to help (see Warneken & Tomasello, 2009) and might help a harmful actor if that were their only option; the forced-choice paradigm gave them the option of not helping the actor. Finally, once children had helped one person in the helping test, they were given the opportunity to help the other person if they chose so.

Study 1

In Study 1, children saw the actor harming, helping, or, as a baseline measure, behaving neutrally toward the recipient. We predicted that children's subsequent helping would be mediated by the actor's behaviors toward the recipient.

Method

Participants

Participants were 3-year-olds ($N = 54$; 9 girls and 9 boys per condition) between 35 months 21 days and 38 months 17 days ($M = 37$ months 11 days, $SD = 22.46$ days) from a medium-sized German city. Fifteen additional children were tested but excluded because of indecisiveness or unclear responses during the helping test (6; see the Procedure section for a description of a clear helping response), fussiness or inattentiveness (4), parents not following instructions (4), and experimenter error (1). Children were recruited from a database of parents who volunteered to participate in child development studies. Participants were all native German speakers and came from mostly middle-class backgrounds. Although precise information about the sample's ethnicity is not available, about 98% of the population from which the sample was drawn is native German. All children were seen in a child laboratory for a 45-min ''play'' session. The same three adult female experimenters played the same roles (of recipient, actor, and neutral person) for all children.

Materials and Setting

The setup is shown in Figure 1. Each child saw four familiarization trials during which the child, recipient, and actor sat around a table; the neutral person sat to the side, visible to the child, reading a magazine. The following materials were used during familiarization trials: two necklaces with colorful beads, two belts with colorful beads, blank sheets of paper and a color pencil, and a blue and a red ball of clay in a container.

In the subsequent helping test, two identical color-matching games were used which consisted of a box with four holes marked by different colors into which balls of matching colors could be placed. The child stood at a predetermined location and the color-matching games' boxes were placed 2 m from and on either side of the child (see Figure 1). Next to each box lay three of the four balls required for each game; a blue ball was missing from both sides. One blue ball lay in the middle, 1 m from the child. The parents sat directly behind the child, the actor and neutral person sat next to their game (side counterbalanced across children), and the recipient stood to the side of and behind the child, facing away from the interaction, and kept time.

Procedure

After warming up with the children, the recipient introduced the actor and neutral person to children as her friends. The actor and neutral person then warmed up with children, being careful to interact equally and similarly with them. Throughout, the recipient wore one of the necklaces and belts described before. After about 10 min in the warm-up room, the recipient told children that she would like to show them the toys in a different room, and escorted the children and parents to the testing room, followed by the actor and the neutral person.

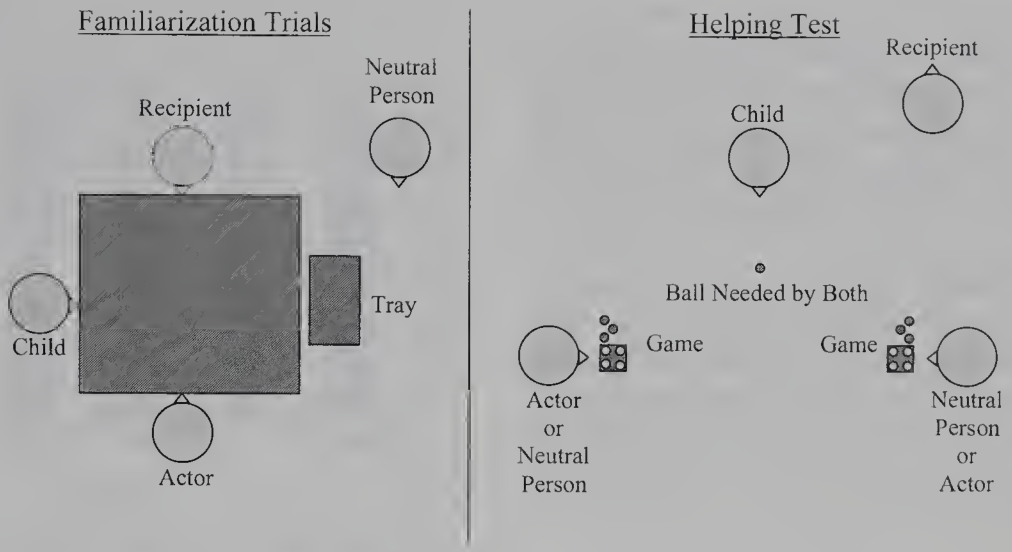

Figure 1. Experimental setup for all conditions.

The study was between-subjects with three conditions (harm, help, and baseline). All conditions had four familiarization trials followed by one helping test. Each familiarization trial (adapted from Vaish, Carpenter, & Tomasello, 2009) began with a 45-s presentation in which the recipient presented one of the following objects (order counterbalanced):

Necklace and belt. The recipient admired and showed off her necklace or belt. A second necklace and belt lay on a tray, visible but inaccessible to children.

Picture. On one sheet of paper from the stack, the recipient drew a picture, proudly commenting on how pretty it was and how happy it made her.

Clay. Using one ball of clay, the recipient made a bird, commenting as in the picture trial. The second clay ball remained in the container.

These 45-s presentations ended differently depending on the condition: In the harm condition, the recipient placed her possession on the table and the actor said in a mildly aggressive tone, "I'm going to take [or tear or break] this now," and put on the necklace or belt, or tore up the picture or bird and threw the bits into a bin. The actor did not display aggression in her facial expression (which was neutral while she spoke and during her actions), nor in any other way before or during her actions. The recipient watched the actor sadly but silently. After 15 s, the recipient assumed a neutral expression and began the next demonstration.

In the help condition, in contrast, the recipient was accident-prone: Instead of placing her possession on the table, she accidentally dropped her necklace, detached beads from her belt, tore her picture, or damaged her clay bird, and was sad about each mishap. The actor said sympathetically, "I'll get [or fix] it," then retrieved or repaired the object. The recipient watched the actor sadly but silently (as in the harm condition). After 15 s, the actor placed the object on the table and smiled, and the recipient happily took it, put it aside, and neutrally began the next demonstration.

The baseline condition established the appropriate chance level for analyses of the other conditions and thus involved the actor behaving neutrally. After necklace and belt demonstrations, the recipient told the children that the necklace (or belt) on the tray was not hers. The actor then commented on the necklace or belt on the tray ("The necklace has so many beads" or "This belt can be adjusted here") and counted the beads or adjusted the belt. After picture and clay demonstrations, the actor said, "These [remaining] sheets are all blank" or "This [second ball of] clay is stuck to the container," and proceeded to examine the paper or unstick the clay. The actor's comments and expression were neutral and the recipient watched the actor neutrally. After 15 s, the actor put the object away and the recipient began the next demonstration.

In each condition, the familiarization trials were followed by a helping test in which the actor and neutral person simultaneously but individually played their respective color-matching game. After placing the three available balls in their slots, both simultaneously reached for the ball in the middle and maintained this reach, looking only at the ball. If children did not act within 15 s, the recipient silently cued parents to ask children to "give the ball." If this was ineffective, parents asked children to point to the person they wanted to give the ball to. As a last resort, the recipient sat between the actor and neutral person, held up the ball, and asked children to give it or point to the person they wanted to give it to. Whomever children chose gratefully accepted the ball. Only placing the ball in or near one person's hand or pointing to one person were considered clear responses. If children did not respond within 1 min, the test was ended.

After the helping test, children received a second ball to hand to whomever they chose. This helped resolve the situation by giving children the chance to help both individuals. Finally, in the harm condition, the actor made amends (e.g., by returning the recipient's necklace and belt) and apologized, and the recipient accepted the apology.

Coding and Reliability

During testing, the primary author coded to whom children chose to give the ball. A second coder (blind to condition and hypotheses) coded this measure from videotapes for a random 50% of children (9 per condition). Agreement was perfect, $\kappa = 1.0$. For the same 50%, before giving the code, the second coder judged (using relevant cues such as one person reaching slightly further than the other) whether either person was likelier to receive the ball. She judged the actor as likelier in seven cases and the neutral person in five cases, but these numbers were unrelated to condition and to who received the ball (Fisher's exact tests, *p*s = .47 and 1.00, respectively).

Results

As preliminary analyses revealed no gender effects, gender was not included in further analyses. All reported *p* values are two-tailed. In the baseline condition, 12 of 18 children (67%) helped the actor; 67% was thus the appropriate test proportion for the other conditions. Following Hamlin et al. (2007), we used binomial tests to analyze the experimental conditions. In the harm condition, a significantly lower proportion of children than 67% helped the actor (4 of 18, or 22%; binomial probability, $p < .0005$). This difference did not emerge in the help condition (11 of 18 children, or 61%, helped the actor; binomial probability, $p = .760$; see the first three bars of Figure 2).

Secondary analyses using chi-square tests revealed that the harm condition differed significantly from the baseline condition, $\chi^2(1, N = 36) = 7.20$, $p = .007$, and from the help condition, $\chi^2(1, N = 36) = 5.60$, $p = .018$. The help and baseline conditions did not differ, $p = .729$.

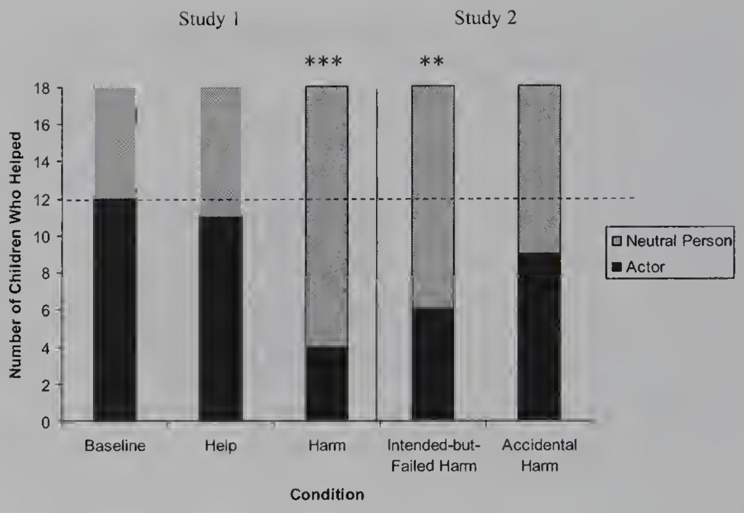

Figure 2. Number of children who helped the actor or the neutral person in Studies 1 and 2.
Note. The dashed line represents chance (67%) as established by the baseline condition.
$^{**}p < .01$. $^{***}p < .0005$.

An alternative explanation for the results of the harm condition is that children refrained from helping the actor because they were afraid of her (e.g., because of her mildly aggressive tone of voice). However, the phase in which children received a second ball suggests otherwise: All 14 children who had first helped the neutral person gave the second ball to the actor, indicating they were not afraid of her but, when forced to choose during the helping test, chose not to help her.

Discussion

This study showed that 3-year-olds take into account others' harmful behaviors toward third parties when deciding whether or not to help them. This extends Olson and Spelke's (2008) findings to children's own prosocial behavior and suggests that children select whom to help and selectively direct resources away from harmful people.

The actor's harmful but not her helpful actions impacted children's behavior. This suggests a negativity bias, that is, a greater impact of negative than of positive information. This bias has been extensively documented in adults (e.g., Baumeister, Bratslavsky, Finkenauer, & Vohs, 2001) and in children's social-emotional development (Vaish, Grossmann, & Woodward, 2008). Our findings suggest a similar bias in children's moral development: Children's prosocial behavior is decreased toward a harmful individual but not increased toward a helpful individual. This result is consistent with the research on children's moral judgments that indicates that children correctly identify "bad" acts substantially earlier than "good" acts (Hill & Hill, 1977; Rhine, Hill, & Wandruff, 1967; see Karniol, 1978; Smetana, 2006; Turiel, 2006, for discussions). Future studies should further explore the origins and implications of the negativity bias in moral development (see Aloise, 1993; Leslie, Knobe, & Cohen, 2006, for relevant work).

Notably, although most children in the harm condition helped the neutral person first, they handed a second ball to the actor. This concords with Olson and Spelke's (2008) finding that although 3.5-year-olds allocated resources selectively when resources were limited, when resources were sufficient, children divided them equally among recipients, displaying a sense of fairness. When a second ball was available, children in our study also displayed fairness, or at the very least, they were willing to help the actor when she was the only one who needed help.

In Study 1, young children helped a harmful individual less, but whether this was in response to the individual's harmful intentions or to the negative outcomes she caused remains unclear because the harm condition featured both intentional harm and negative consequences. The critical question of why children helped a harmful actor less was addressed in Study 2.

Study 2

The intention–outcome distinction is essential to the study of moral development, given that sophisticated moral judgments are thought to rely on not only the consequences of but also the intentions behind others' behavior (Cushman, 2008; Karniol, 1978; Piaget, 1932/1997; Turiel et al., 1987). Developmental work suggests that when intentions and outcomes are pitted against each other, children around 5 years of age and above reliably use the perpetrator's intentions when making moral judgments and assigning punishment; prior to this, they rely largely on outcome information (e.g., Miller & McCann, 1979; Wellman, Larkey, & Somerville, 1979; Zelazo, Helwig, & Lau, 1996). Much of this past work has assessed children's verbal evaluations of hypothetical moral transgressions, which may not be optimal for very young children whose language skills are limited and which do not always correspond to children's actual behavior (Astington, 2004; Darley & Shultz, 1990; Wainryb, Brehl, & Matwin, 2005). We asked in our second study whether young children's ability to respond to the intentions behind moral transgressions might be evident in their prosocial behavior.

In Study 2, we teased apart intentions and outcomes using two new conditions: In the intended-but-failed harm condition, the actor intended but was unable to harm the recipient (non-negative outcome, negative intention), and in the accidental harm condition, the actor accidentally harmed the recipient (negative outcome, non-negative intention). If the intentions behind others' harmful actions mediate children's prosocial behavior, children should subsequently help the actor less than the neutral person in the intended-but-failed harm condition but not in the accidental harm condition.

Method

Participants

Participants were 3-year-olds ($N = 36$; 9 girls and 9 boys per condition) between 35 months 18 days and 38 months 15 days ($M = 37$ months 7 days, $SD = 24.93$ days). Seven additional children were tested but excluded because of indecisiveness or unclear responses during the helping test (3), fussiness or inattentiveness (2), parent not following instructions (1), and experimenter error (1). Participant recruitment, the sample's ethnicity and socioeconomic backgrounds, and the duration of sessions were the same as in Study 1. The same experimenters played the same roles as in Study 1.

Materials and Setting

The materials were the same as in Study 1 with minor changes. In the intended-but-failed harm condition, the sheets of paper had a border of transparent tape such that they could not easily be torn. In the accidental harm condition, a set of beads was wrapped around the belt such that it could easily fall off, and the sheets of paper had an inconspicuous rip such that they could easily tear. The setting was identical to Study 1.

Procedure

The warm-up session was identical to Study 1. The two between-subjects conditions of Study 2 again involved four familiarization trials and a helping test. The recipient's presentations during familiarization trials were similar to Study 1 except that she decorated her clay bird with beads. The four 45-s presentations ended with the recipient placing her possession on the table. In the intended-but-failed harm condition (like the harm condition), the actor then said mildly aggressively, "I'm going to tear [or break] this now," and attempted (with obvious effort) to tear up the picture, dislodge the beads from the clay bird, or break the necklace or belt. She did not display aggression facially or in any other way before or during her actions. Importantly, she was unable to cause harm as she could not tear through the tape around the paper, the beads were lodged too deeply into the clay, and pulling on the beads of the necklace and belt did not break them off. The recipient watched the actor sadly but silently. After 15 s, the actor gave up and placed the object back on the table. The recipient examined the object, smiled briefly (to indicate satisfaction that it was intact), placed it to the side, and neutrally began the next presentation.

In the accidental harm condition, the actor accidentally destroyed the recipient's objects. Thus, the actor admired the picture but accidentally tore it while returning it to the recipient. Similarly, the beads fell off the belt and the knot of the necklace came undone while she was admiring these objects. In the clay situation, the actor was looking at her watch when the bird was placed on the table so that when she turned to admire the bird, her arm collided with it and broke it. After each mishap, the actor said in a sorry tone of voice, "I didn't want that to happen" or "That wasn't on purpose" (in alternating order, beginning with the former). The actor apprehensively examined the broken object but did not repair it or apologize, and the recipient watched the actor silently but sadly. After 15 s, the actor placed the object to the side and the recipient neutrally began the next presentation.

As in Study 1, familiarization trials were followed by a helping test and a final phase in which children could hand over a second ball. Finally, in the intended-but-failed harm condition, the actor apologized and the recipient accepted the apology.

Coding and Reliability

Coding and reliability were conducted as in Study 1. Agreement was perfect between the primary and second coders' coding of whom children gave the ball to, $\kappa = 1.0$. The second coder also judged that the actor was more likely to receive the ball in one case and the neutral person in four cases, but these numbers were unrelated to condition and to who received the ball (Fisher's exact test, *p*s = .40 and 1.00, respectively).

Results

As preliminary analyses revealed no gender effects, gender was not included in further analyses. All reported p values are two-tailed. We again used the test proportion (67%) established by the baseline condition in Study 1. Binomial tests revealed that in the intended-but-failed harm condition, a significantly lower proportion of children than 67% helped the actor (6 of 18, or 33%; binomial probability, $p = .008$). This difference did not emerge in the accidental harm condition (9 of 18 helped the actor, $p = .204$; see the last two bars of Figure 2).

Chi-square analyses revealed that the intended-but-failed harm condition differed significantly from the baseline condition of Study 1, $\chi^2(1, N = 36) = 4.00, p = .046$, but not from the harm condition, $p = .457$. In contrast, the accidental harm condition differed marginally from the harm condition, $\chi^2(1, N = 36) = 3.01, p = .083$, but not from the baseline condition, $p = .310$.

Results from the final (second ball) phase again suggest that children were not afraid of the actor in the intended-but-failed harm condition: Of the 12 children who helped the neutral person during the helping test, 10 handed the second ball to the actor.

Discussion

In Study 2, 3-year-olds decreased their prosocial behavior toward a person who had harmful intentions toward a third party even if she did not cause negative outcomes. Moreover, children did not significantly decrease their prosocial behavior toward a person who caused negative outcomes without harmful intentions. These findings are the first evidence that by age 3, children selectively reduce prosocial behavior toward intentionally harmful—and thus morally blameworthy—individuals regardless of the consequences of those individuals' actions.

Study 2 contributes to the moral development literature as it suggests that as early as 3 years, children respond differently to intentionally versus unintentionally caused harm. In prior work in which intentions and outcomes were pitted against each other in hypothetical moral transgressions, children reliably used a perpetrator's intentions in their moral evaluations starting around 5 years of age (e.g., Wellman et al., 1979; Zelazo et al., 1996). Interestingly, however, Imamoğlu (1975) found that even when older children (5-year-olds) fail to differentially evaluate intentional versus accidental acts, they respond differentially on other measures such as like–dislike judgments of the perpetrator. Thus, young children's understanding of a perpetrator's intentions may be more apparent in their liking of or willingness to help the perpetrator than in their verbal evaluations of the transgression. Affiliation and helping may thus be precursors to and important facets of children's moral evaluations. More generally, nonverbal, nonhypothetical behavioral measures complement verbal measures of children's judgments and reasoning about intentions. Future work should accordingly employ both verbal and behavioral measures focusing on both the act and the actor to obtain a fuller picture of children's moral judgment-making.

General Discussion

The present studies demonstrate that young children's prosocial behavior is mediated by others' moral behavior. In Study 1, 3-year-olds helped a harmful adult less than a neutral adult, extending Olson and Spelke's (2008) findings to children's own prosocial behavior. The important new finding from Study 2 was that 3-year-olds grasped the intentions behind harmful behavior and selectively decreased their prosocial behavior toward the actor if and only if she could be held morally responsible for her actions (i.e., when she had harmful intentions), even if she was unsuccessful in causing harm. Thus, by age 3, children selectively withhold help from morally blameworthy individuals.

It could be argued that children in the harm and intended-but-failed harm conditions helped the actor less because of her mildly aggressive tone of voice rather than her harmful behavior. However, some aggression is likely a reliable cue to intentional as opposed to accidental harm. Indeed, our rationale for including mild aggression was that having the actor speak entirely neutrally would create an unnatural harming situation in which the actor's intentions would be ambiguous. For instance, children might infer from a neutral voice that the actor had not registered or did not remember that the objects belonged to the recipient and she thus did not intend harm. Thus, although future studies could control for the actor's aggression, we argue that some mild aggression is naturally linked with intentionally harmful behavior and retaining it creates a more ecologically valid situation.

There are also several reasons to believe that the actor's mild aggression alone does not explain the results. First, the actor was only aggressive in her tone of voice and only before the transgressions, not in any other way or at other times during the procedure. Also, nearly all children in both the harm and intended-but-failed harm conditions gave a second ball to the actor, suggesting that her aggression had not made them afraid of her (though it is possible that children were afraid of the actor but their fear did not stop them from helping her in this context). Finally, in a recent study exploring children's protest against moral transgressions (Vaish, Missana, & Tomasello, in press), a puppet proclaimed her harmful intentions (to tear another puppet's drawing because she did not like it) in the same neutral, nonaggressive way in which she proclaimed her nonharmful intentions (to tear a blank piece of paper because she did not like it). Three-year-olds nevertheless protested more in the harmful than in the neutral case. Thus, young children do recognize moral transgressions even in the absence of aggression, at least when the transgressor provides another reason for the transgression (not liking the drawing). It is thus unlikely that our findings are due solely to the slightly aggressive way in which the actor spoke before her harmful actions.

In the present studies, children directed less helping toward a person who harmed or intended to harm a third party. A similar result emerges in adults: In economic games, adults punish individuals who show unfair behavior even when they were not themselves affected by that behavior (Fehr & Fischbacher, 2003, 2004; Singer et al., 2006). Our findings show that the ability to identify harmful individuals and to withhold help from them emerges early in childhood, although it remains unclear whether children actively punished the harmful actor or more passively shunned or avoided her.

Our results are limited to children's interactions with adults and may not generalize to children's interactions with their peers (see, e.g., Killen, 1991). Numerous authors have observed that child–child interactions provide a rich and unique context within which children develop a sense of fairness, equality, and justice (e.g., Arsenio & Lover, 1995; Damon & Killen, 1982; Dunn, Cutting, & Demetriou, 2000; Piaget, 1932/1997; see Smetana, 2006). Thus, when in such interactions, children may display a more advanced command of these concepts and at still younger ages than we have shown here. Alternatively, our use of child–adult interactions in a laboratory may have made children comply with what they perceived as the adults' expectations. Note, though, that our helping measure did not entail providing responses about the moral transgressions directly to an adult; rather, it was a more implicit assessment that took place after, and in a different situation than, the transgressions. Children's responses are thus unlikely to have been influenced much by their perceptions of the adults' expectations. Still, on the view that children were complying with such expectations, children may not show the same sensitivity in interactions with other children. Even so, our findings at least demonstrate young children's ability to recognize harmful intentions in interactions with adults under controlled conditions. It remains for future research to assess this ability across multiple contexts and types of interactions.

Relatedly, although we assessed the impact of the intentions behind and outcomes of moral behavior, we recognize that these are only two of several criteria that fall under only one of several domains that impact children's moral judgments. Other criteria in the moral domain include, for instance, whether the perpetrator apologized and whether she was already punished (e.g., Miller & McCann, 1979). Criteria in the psychological domain include the victim's and the children's own relationship with the perpetrator (e.g., Slomkowski & Killen, 1992; Wellman et al., 1979). The context of the transgression and individual differences among children also play a role, and of course, all of the aforesaid domains and factors interact with each other (see Helwig, 2006; Killen, 2007; Smetana, 2006, for reviews). Intentions and outcomes thus form only one piece of the rich and multifaceted area of children's moral judgments.

Furthermore, we broadly used the term *moral behavior* throughout to mean acts that have consequences for others' rights or welfare (e.g., Smetana, Schlagman, & Adams, 1993). Morality certainly includes other criteria, such as obligation and independence from authority sanctions, which distinguish it from the conventional, psychological, and personal domains of social knowledge (e.g., Smetana, 2006; Turiel et al., 1987). Our focus here, however, was on whether children's prosocial behavior is mediated by an individual's harmful transgressions against others. Although these are precisely the types of transgressions that fall into the moral domain, our focus on prosocial behavior rather than on moral judgments precluded an assessment of whether children perceived the transgressions as moral in the strict sense or not. Children may have withheld help for many reasons (such as how much they liked the perpetrator) that are related to but not the same as judging the transgressions to be moral. All the same, children's ability to recognize harmful behaviors and intentions as seen in their prosocial behavior might be an early step on the way to the full-blown, explicit moral judgments that children make just a few years later and as such, is important to explore.

Finally, to say that children's prosocial behavior is mediated by others' harmful behaviors and intentions is not to disregard the many additional mediating factors. For instance, there is evidence for a direct reciprocity effect on the sharing behavior of 3-year-olds (Levitt, Weber, Clark, & McDonnell, 1985; Olson & Spelke, 2008). Sympathy for the potential beneficiary also plays a role (see Eisenberg & Miller, 1987; Vaish et al., 2009). Overall, the emerging picture is that early in development, children begin engaging in sophisticated social and moral evaluations that impact their own prosocial behavior.

Prospective Associations Between Peer Victimization and Aggression

Jamie M. Ostrov
University at Buffalo, The State University of New York

The current study involved a short-term longitudinal study of young children (M = 44.56 months, SD = 11.88, N = 103) to test the prospective associations between peer victimization and aggression subtypes. Path analyses documented that teacher-reported physical victimization was uniquely associated with increases in observed physical aggression over time. The path model also revealed that teacher-reported relational victimization was uniquely associated with statistically significant increases in observed relational aggression over time. Ways in which these findings extend the extant developmental literature are discussed.

The study of peer victimization has become an important focus for psychologists who attempt to understand the etiology, course, and outcomes associated with various forms of psychopathology including aggressive behavior in children (e.g., Hanish & Guerra, 2000; Hodges & Perry, 1999; Juvonen & Graham, 2001; Schwartz, McFadyen-Ketchum, Dodge, Pettit, & Bates, 1998; Troop-Gordon & Ladd, 2005). Rather than focusing on the developmental antecedents of peer victimization, the present study focuses on aggression as an important hypothesized outcome associated with peer victimization. Importantly, peer victimization (i.e., chronic or frequent receipt of aggression from peers over time) is associated with increases in physical aggression (i.e., the use or threat of physical force to hurt, harm, or injure another person; Dodge, Coie, & Lynam, 2006) over time in school-aged samples (Graham & Juvonen, 1998; Hanish & Guerra, 2000, 2002; Hodges, Boivin, Vitaro, & Bukowski, 1999; Khatri, Kupersmidt, & Patterson, 2000; Kochenderfer-Ladd, 2003; Schwartz et al., 1998). In fact, Hanish and Guerra (2002) proposed that peer victimization might be a risk factor for subsequent serious adjustment issues (e.g., externalizing behavior) because children who are victimized may have limited opportunities for peer interactions and developmentally salient socialization experiences. Thus, the focus of the present manuscript is testing if peer victimization predicts increases in aggressive behavior for young children. To further test this fundamental question we also examine if the developmental paths from victimization to aggression are present for both physical and relational victimization in early childhood.

Theories have been posited that relational victimization may be associated with increases in relationally aggressive behaviors in which the relationship serves as the means of harm (e.g., threatening friendship withdrawal or direct social exclusion; Crick & Grotpeter, 1996). Two additional conceptually related but distinct forms of aggression include indirect (Lagerspetz, Björkqvist, & Peltonen, 1988; Vaillancourt, Brendgen, Boivin, & Tremblay, 2003) and social (Galen & Underwood, 1997) aggression (see Card, Stucky, Sawalani, & Little, 2008), which were not the focus of the current study. Rose and Rudolph (2006) present a peer-socialization model and are the first known theorists to articulate a conceptual model with potential paths from physical *and* relational peer victimization (i.e., ''exposure to peer stress'') to aggressive behavior (p. 116). According to this model, for example, ''greater exposure to overt or physical victimization may contribute to their vulnerability . . . to aggression. Physical aggression is more appropriate in response to overt victimization than subtle [relational] forms of victimization'' (Rose & Rudolph, 2006, p. 120). In addition, Yeung and Leadbeater (2007, p. 980) asserted that relationally victimized children may respond with relationally aggressive behaviors to hurt the aggressor or avoid further attacks.

The contributions of Emily E. Ries, Jamie L. Guzzo, Kirstin Stauffacher Grös, Stephanie A. Godleski, and the entire UB Social Development Lab staff are greatly appreciated. The author thanks Drs. Julie C. Bowker, Craig R. Colder, and Leonard J. Simms for statistical consultation and feedback on an earlier draft of this manuscript; he also thanks Emily J. Hart and Adam D. Mullins for their comments and suggestions and acknowledges the families, teachers, and directors of participating schools. Preparation of this manuscript was facilitated by a grant (R03HD059781) to the author from the Eunice Kennedy Shriver National Institute of Child Health and Human Development.

Collectively, the contentions that children retaliate in kind (i.e., physical victimization is uniquely associated with physical aggression and relational victimization is uniquely associated with relational aggression) have been articulated as the *specificity hypothesis of aggression* (Crick, Casas, & Ku, 1999; Ostrov, 2008). Young children are posited to be influenced primarily by their own personal experiences (i.e., history of adaptation) of peer victimization and aggression, but they may learn by being a bystander or uninvolved observer of peer interactions if they identify (i.e., label the behaviors as consistent with their self-construal) with the experiences of the salient model (i.e., perpetrator or victim). Thus, a child who is victimized may learn from these interactions and if reinforced will model these self-relevant behaviors increasingly in future hostile interactions with peers. Prior concurrent studies have found support for this hypothesis (Crick et al., 1999; Sullivan, Farrell, & Kliewer, 2006) or limited support depending on the method and informant (Putallaz et al., 2007), but no known prospective analysis has examined the links between both physical and relational victimization and changes in physical and relational aggression, respectively. Thus, the primary goal of the current study was to test if peer victimization uniquely predicted increases in aggression subtypes.

There are only a few known concurrent studies that have studied both aggression subtypes and victimization in early childhood, which is an important developmental period for understanding the onset and subsequent course of peer victimization (e.g., Bonica, Arnold, Fisher, Zeljo, & Yershova, 2003; Crick et al., 1999; Dhami, Hoglund, Leadbeater, & Boone, 2005). Prospective longitudinal studies exploring the association between peer victimization and future aggression subtypes are rare in the extant developmental literature (for exceptions in middle childhood and early adolescence, see Leadbeater & Hoglund, 2009; Schwartz et al., 1998). One recent study, in early adolescence, provided evidence that self-reported relational victimization was significantly associated with future self-reported relational aggression, even after controlling for physical victimization (Yeung & Leadbeater, 2007). To avoid shared-method bias concerns, Yeung and Leadbeater (2007) called for multi-informant sources of data in future work testing these links (see also Prinstein, Boergers, & Vernberg, 2001). As such, the current multi-informant and multimethod study (i.e., teacher report and naturalistic observations) advances the developmental literature by being the first to study how teacher-reported peer victimization subtypes may predict changes in observed aggressive behavior subtypes for young children.

Peer rejection may affect aggression and victimization status (Bierman, 2004; Bierman & Wargo, 1995; Perry, Kusel, & Perry, 1988), and thus, it is important to consider in any peer victimization study. Importantly, peer victimization and rejection are positively related across time, but they are independent constructs (Hodges & Perry, 1999; Perry et al., 1988). Both physical and relational peer victimization have been found to increase a child's likelihood of peer rejection (e.g., Crick & Bigbee, 1998; Hanish & Guerra, 2002), and peer rejection has been associated with increases in aggression subtypes over time (e.g., Werner & Crick, 2004). Aggression and peer victimization are related to peer rejection, but they are often found to be associated with peer rejection for different reasons (Boivin & Hymel, 1997; Perry et al., 1988). Given the moderate to high associations between peer victimization and rejection it is important to test models that include both constructs so that unique associations may be tested (see Morrow, Hubbard, Rubin, & McAuliffe, 2008).

In the present study, aggression is defined as behaviors in which there was the intent to hurt, harm, or injure another person (Dodge et al., 2006). It is well documented in the literature that there are other behaviors that resemble physical and relational aggression, but they do not conform to the definition of aggression. Developmental scholars have called these behaviors: "rough and tumble play," "assertion," or "social dominance," because they explicitly do *not* include the intent to harm others (e.g., Ostrov, Pilat, & Crick, 2006; Pellegrini, 2003). Moreover, exclusion behaviors that are considered fair (e.g., excluding a poor athlete from a sports group; Killen & Stangor, 2001) or actions in which the intent of the child is due only to a desire to play by him- or herself are not examples of relational aggression and were explicitly addressed in training of observers in the present study. It is important to note that children during early childhood (i.e., 3- to 5-year-olds) are able to engage in relatively sophisticated forms of relational aggression (see Crick, Ostrov, & Kawabata, 2007). However, during early childhood, even when these behaviors resemble sophisticated covert actions like spreading a malicious secret, they are direct in nature, based on situations occurring in the present, and the identity of the perpetrator is clearly defined (see Ostrov, Woods, Jansen, Casas, & Crick, 2004).

There were several goals and hypotheses for this study. Our central goal was to test the direct prospective associations between peer victimization subtypes and increases in aggressive behaviors. Based on the adopted conceptual model (Rose & Rudolph, 2006) and the specificity hypothesis of aggression (Crick et al., 1999; Ostrov, 2008), we predicted that peer victimization would be associated with increases in aggressive behavior. More specifically, in keeping with theory, we predicted that physical victimization would be positively and uniquely associated with increases in physical aggression (e.g., Hanish & Guerra, 2002). Further, we anticipated that relational victimization would be positively and uniquely associated with increases in relational aggression (Yeung & Leadbeater, 2007).

Method

Participants

A total of 119 (69 girls) children initially participated in this ongoing longitudinal study (e.g., Ostrov, 2008). Attrition was small (13%, 7 boys and 9 girls) and was because of families who moved out of the area, which yielded a final sample size of 103 children (60 girls). Children were on average 44.56 months old ($SD = 11.88$) at the first time point. Children represented various ethnic backgrounds: 14.6% African American, 14.6% Asian, 59.1% Caucasian, 2.9% Hispanic, 3.9% Indian, 1.0% Native American, and 3.9% other ethnicities. Most children were from middle-class families. Children were recruited in two equal cohorts and there were no statistically significant cohort effects for any of the key study variables ($t = -1.57$–1.19, $p > .12$).

Procedure

The study was approved by the local Institutional Review Board and parents provided written consent prior to participation. Head teachers also provided written informed consent (100% participating) prior to completing teacher reports. The second time point was approximately 4 months after the conclusion of Time 1 (for additional details, see Murray-Close & Ostrov, 2009).

Measures

Observations of aggression. The Early Childhood Observational System introduced by Ostrov and Keating (2004) and revised by Crick et al. (2006) was adopted (for a review, see Leff & Lakin, 2005). Naturalistic focal child sampling with continuous recording of children's relational and physical aggression were conducted during free play at participating child-care centers at both time points. At each of the two time points, every focal child was observed for eight separate sessions (10 min per session), which took place on different days over a 2-month period for 80 min of total observation per child.

Training consisted of several steps (see Ostrov, 2008). Assessments of reliability were conducted throughout the study to avoid observer drift (Pellegrini, 2004). For each 10-min session, the observers recorded, in full detail using a structured observation form: (a) physical aggression (e.g., hitting, kicking, pushing) and (b) relational aggression (e.g., direct verbal [i.e., ''You can't play with me''] or nonverbal exclusion from a group or dyadic interaction [i.e., blocking a child from entering a preferred area], using friendship withdrawal as a threat [i.e., ''You are not my friend anymore'']). Behaviors were summed within category, across the eight sessions, to yield total scores. Interobserver reliability (15% of observations) was acceptable for relational aggression (intraclass correlation coefficients [ICCs] from .72 to .86) and physical aggression (ICCs from .78 to .95). Correlations between teacher-reports and the observations of relational and physical aggression (at both time points) were significant and moderate in nature (see Ostrov, Ries, Stauffacher, Godleski, & Mullins, 2008).

Teacher report of victimization. The Preschool Peer Victimization Measure–Teacher Report (PPVM–TR; Crick et al., 1999) assessed physical and relational victimization at the first time point. This measure includes eight items: Two items assess physical victimization (''This child gets pushed or shoved by peers''), three items assess relational victimization (''This child gets left out of the group when someone is mad at them or wants to get back at them''), and three filler items assess received prosocial behavior. Teachers rated how often focal children were relationally or physically victimized on a 5-point scale ranging from 1 (*never to almost never true*) to 5 (*always or almost always true*). The items were summed within category. In the current study, Cronbach's αs = .85 and .90 for relational and physical victimization, respectively. Moderate levels of stability were found for both subscales, and in this sample the validity of the measure has been supported by replicating the original predicted factor structure and by obtaining significant correlations between teacher and research assistant (RA) reports for both subtypes of victimization (Ostrov, 2008).

Teacher report of peer rejection. The Preschool Social Behavior Scale–Teacher Form (PSBS–TF; Crick, Casas, & Mosher, 1997) was used to assess peer rejection (e.g., Crick et al., 2006). Using the aforementioned 5-point scale, teachers reported how disliked children were by same and opposite-sex peers (two summed items). This measure had acceptable reliability in the past (e.g., Crick et al., 2006) and in the current study was internally consistent at both times (Cronbach's $\alpha > .88$). Teacher-reported peer rejection was moderately stable across the study and teacher- and RA-reported peer rejection were significantly correlated (Ostrov, 2008).

Results

We first conducted descriptive statistics for the study variables (see Table 1). Two outliers (> 3 *SD*) were detected for observed relational aggression at Time 2 and these values were replaced with the value of 3 *SD* above the mean (Kline, 1998). Skew was less than 2 and kurtosis was lower than 8 for all variables, suggesting that non-normality of the data was not a concern (Kline, 1998). We also conducted correlations between the study variables (see Table 1). To avoid being underpowered for testing effects at the level of gender, only the total sample was used in this study. Importantly, physical victimization was significantly associated with future physical aggression ($r = .35$, $p < .001$) and relational victimization was significantly correlated with future relational aggression ($r = .27$, $p = .007$). Both physical and relational victimization were significantly correlated with peer rejection. Next, Fisher's r to Z tests were conducted to examine differences in the association between variables. The correlation between relational victimization at Time 1 and relational aggression at Time 2 ($r = .27$, $p = .007$) was significantly higher than the correlation between physical victimization at Time 1 and relational aggression at Time 2 ($r = .03$, *ns*), $Z = 2.21$, $p < .05$. It was also found that the association between peer rejection at Time 1 and relational victimization at Time 1 ($r = .56$, $p < .001$) was significantly higher than the corresponding association between peer rejection and initial physical victimization ($r = .24$, $p = .013$), $Z = 3.42$, $p < .01$.

Observational methods that rely on multiple observers and several sessions have often generated lower levels of intercorrelation between aggression subtypes than other approaches that may have higher levels of association as a result of shared method variance (see Ostrov & Crick, 2007). It is also conceivable that the amount of overlap even with teacher reports for 3- to 5-year-olds (e.g., .46 for boys and .37 for girls reported in Crick et al., 1997) is lower than for children in older developmental periods (e.g., .77; Crick, 1996) because physical aggression may be more common than relational aggression in this developmental period (see NICHD Early Child Care Research Network, 2004). In the present study, similar to past findings, the intercorrelation between observed physical and relational aggression was low and the intercorrelation between teacher-reported physical and relational victimization was moderate in magnitude (see Table 1).

To test the key hypothesis of the study a path analysis model with maximum likelihood estimation using Lisrel 8.54 was conducted (see Figure 1). In keeping with common practice in the field, in the tested models, age was entered as a covariate (e.g., Bonica et al., 2003; Crick et al., 2006; Hart, Nelson, Robinson, Olsen, & McNeilly-Choque, 1998). Models with and without gender as a covariate were virtually identical, and thus, the more parsimonious model without gender is presented. In keeping with recommendations of Hu and Bentler (1999) the standardized root mean square residual

Figure 1. Path analysis model predicting changes in observed physical and relational aggression.
Note. Standardized path coefficients are shown. Covariance paths (see text) and disturbances, as well as the covariate age, are not shown for ease of communication. The model fit was acceptable, $\chi^2(5) = 6.36$, $p = .27$; root mean square error of approximation = .053, standardized root mean square residual = .037, comparative fit index = .99.
$^*p < .05$. $^{**}p < .01$. $^{***}p < .001$.

(SRMR) and the comparative fit index (CFI) were used to evaluate goodness of model fit. A cutoff of .08 or lower for SRMR and a value of .95 or larger for the CFI is viewed as a good fit (Hu & Bentler, 1999). The SRMR and CFI have been found to provide an appropriate balance between Type I and II error rates (Hu & Bentler, 1999). In addition, in keeping with standard reporting practices, the root mean square error of approximation (RMSEA) is also reported and acceptable values are considered less than .06 (Hu & Bentler, 1999).

The first model tested was the hypothesized model and the goodness-of-fit indices were acceptable, $\chi^2(5) = 6.36$, $p = .27$; RMSEA = .053, SRMR = .037, CFI = .99. The hypothesized model was compared with a more specified model but the additional two paths (i.e., between physical aggression at Time 1 and future relational aggression as well as from relational aggression at Time 1 to future physical aggression) were not significant. The model fit of this more specific model was generally adequate although the RMSEA was outside the acceptable range, $\chi^2(3) = 5.51$, $p = .14$; RMSEA = .093, SRMR = .030, CFI = .98. The $\Delta\chi^2$ test between the nested models was not significant, $\Delta\chi^2(2) = .85$, *ns*. In keeping with standard practice, the more parsimonious, hypothesized model was adopted. Importantly, the parameter estimates were similar and the same paths were significant in the two models. The adopted model also included (not shown in Figure 1 for ease of communication) a covariance between each of the predictor constructs and a covariance between the residuals of the outcome variables (i.e., physical and relational aggression at Time 2). We included initial levels of observed physical and relational aggression in the model so that testing increases in aggressive behavior over time could be analyzed. Importantly, as hypothesized, physical victimization was significantly associated with increases in physical aggression. In addition, as hypothesized, relational victimization was associated with significant increases in relational aggression (see Figure 1).

Discussion

The central study goals were to examine the prospective associations between peer victimization subtypes and future aggression subtypes. Rose and Rudolph (2006) posited that physical aggression rather than more subtle forms of behavior like relational aggression would be a more appropriate behavioral response to physical victimization. In keeping with the peer-socialization model (Rose & Rudolph, 2006) and past research (Hanish & Guerra, 2002), we found that peer physical victimization was associated with increases in physically aggressive behavior across time. Moreover, responding with the same behavior in kind has been posited for relational forms of behavior as well (see Yeung & Leadbeater, 2007). In keeping with these predictions and the *specificity hypothesis of aggression* (Crick et al., 1999; Ostrov, 2008), we found that teacher-reported relational victimization was associated with increases in observed relational aggression. Given the moderate and significant overlap between relational victimization and peer rejection, it is important to note that the conservative model also controlled for the influence of peer rejection (Morrow et al., 2008). Thus, it is not just that these children are rejected by their peers, which directly leads to changes in aggressive behavior; rather, the current findings suggest that experiencing victimization is a unique predictor of increases in aggression. Moreover, the present findings suggest that children who are victimized may learn from these interactions and adopt behaviors from salient social models (see Rose & Rudolph, 2006). Finally, if these actions are reinforced over time, presumably because they are effective at reducing peer victimization and facilitating goal obtainment such as social status, the child may continue to increase in his or her rate of aggression.

The present study addressed theoretically driven hypotheses with a multi-informant and multimethod short-term longitudinal study. Despite the strengths of this approach and use of time-intensive observational methods, the current study is limited in several ways. First, we were unable to explore moderation by gender analyses because we were underpowered for testing these effects and future work should examine models for both boys and girls with a larger and more diverse sample (see Card et al., 2008). Second, additional time points would have permitted an examination of growth trajectories in the development of both aggression and victimization and would have permitted more robust estimates of the present effects. Third, it is conceivable that earlier aggressive behavior may have predicted peer victimization, which in turn predicts increases in aggression. That is, physically (or relationally) aggressive children may receive more physical (or relational) retaliation which in turn, contributes to increases in his or her own aggression. Future longitudinal work with earlier assessments is needed to test these additional feasible pathways. Fourth, multiple methods (e.g., peer ratings or nominations, observations) for assessing victimization subtypes should be conducted in future studies (Kochenderfer & Ladd, 1997).

The current findings raise several implications for future research. The present study indicates that our past understanding of how victimization and aggression are linked across time may need to be revised. That is, a large amount of theory and research has focused exclusively on prospective links from aggression to victimization (for two exceptions, see Leadbeater & Hoglund, 2009; Schwartz et al., 1998). In fact, past social process models of peer harassment have posited that relatively stable behavioral tendencies like aggressive behavior may directly or indirectly lead to peer victimization via peer rejection (Boivin, Hymel, & Hodges, 2001). The current study used multiple methods and high levels of statistical control to examine the reverse direction of effect and found prospective links from peer physical victimization to physical aggression during early childhood, even with peer rejection in the model. We are also the first known study to reveal that relational victimization may uniquely lead to increases in relational aggression among young children. Thus, we may tentatively conclude a unique link between exposure to peer stress/harassment and increases in aggression over time (Rose & Rudolph, 2006). More specifically, we have demonstrated initial prospective support for the specificity hypothesis of aggression (Crick et al., 1999; Ostrov, 2008). Replication of the specificity hypothesis of aggression is needed with more diverse samples. In addition, the extent to which the children in the current study were provocative victims or aggressive victims (i.e., high in both aggression and victimization) with associated emotional and behavioral regulation problems is unknown and requires further investigation (see Schwartz, 2000; Schwartz, Dodge, Pettit, & Bates, 1997; Schwartz, Proctor, & Chien, 2001).

Several implications for future intervention and prevention efforts are raised by the current study. The findings suggest that children who are physically or relationally victimized by their peers may be at risk for displaying increases in school-based aggression over short periods of time. Interventions designed to reduce peer victimization in early childhood classrooms should be developed to minimize the likelihood of this future occurrence and should convey effective strategies for handling peer victimization other than retaliation (i.e., reframing social cognitions and social goals, notification of a teacher or caregiver). That is, school-based early childhood intervention efforts will likely be enhanced if programs explicitly address both peer victimization and aggression subtypes among peers (see Leadbeater, Hoglund, & Woods, 2003). Developmentally appropriate, early prevention would center on facilitating prosocial and friendship formation skills, while also reducing words and actions that cause harm (see Ostrov et al., 2009). In addition, these early childhood programs should be designed to foster a culture in which physical and relational aggression (e.g., malicious social exclusion) are not acceptable (see Harrist & Bradley, 2003). These programs should also provide children with effective tools to decode and distinguish harmful, intention acts from benign behaviors (e.g., exclusivity among close friends; see Leff et al., 2009).

In conclusion, the present study builds on prior theory and research to test novel empirical questions concerning the prospective associations between peer victimization and aggression. Specifically, the present study highlights the importance of understanding peer victimization to predict increases in aggressive behavior in young children.

Development in Children's Comprehension of Linguistic Register

Laura Wagner

Rebecca Gillespie
Xavier University

For socially appropriate communication, speakers must command a variety of linguistic styles, or *registers*, that vary according to social context and social relationships. This study examined preschool children's ability to use a speaker's register choice to infer the identity of their addressee. Four-year-olds could draw correct inferences based on Spanish and formal speech, and had limited success with infant-directed and casual styles. Five-year-olds drew appropriate inferences with all 4 styles; moreover, these children demonstrated strong explicit understanding of register, as measured through response justifications. These results demonstrate that children can use language for social judgments that extend beyond evaluating the speaker, and can interpret social implications of language even when not directly engaged in the particular social interaction.

We talk to different people differently. The speech style used to talk to a baby would be a strange way to address one's doctor and we do not talk to our employers the same way we talk to friends and peers. To engage in socially appropriate communication, we must command a variety of linguistic styles, or *registers*, that vary according to social context and our particular social relationship to the person we are speaking to. Part of acquiring a language, therefore, is learning what different linguistic registers signal about the social context as well as how to combine various linguistic elements into coherent register styles. The study reported here is an examination of children's developing skill at drawing inferences about the identity of a speaker's addressee based on the register that the speaker chooses to use.

Recent work has shown that young children are aware that language is a relevant indicator of social information. Kinzler, Dupoux, and Spelke (2007) found that 10-month-old infants prefer to take a toy from an adult that speaks their native language as opposed to a foreign language, and preschool-age children prefer to play with children who share their language natively, as opposed to speaking it with a foreign accent. Indeed, this social preference for people who speak the same way as oneself may even be stronger in some cases than a social preference for people of one's own race (Kinzler, Shutts, DeJesus, & Spelke, 2009). These results suggest that children understand how language is a marker of group affiliation; people who speak like you (or your parents) are part of your own group.

In many instances, language is in fact a stable trait of the speaker: people who are non-native speakers of English will generally remain that way. Certainly, they will not suddenly become native speakers of English just because they are given a new conversational partner. Native language (or native dialect) is therefore a good marker about stable properties of a speaker, such as where they are from. By contrast, linguistic register provides social information that shifts flexibly depending on the situation. The very same person speaks in one register when talking to an infant and a completely different register when speaking to her boss. Every individual must command a variety of linguistic registers to accommodate a variety of social situations. Identifying a specific register, therefore, tells one little about who the speaker is in general but

---

Special thanks are due to the Center for Science and Industry of Columbus, OH, where initial versions of this study were piloted. The data reported here served as the basis for the second author's honors thesis. Preliminary findings were presented at the International Association for the Study of Child Language conference held in Edinburgh, Scotland in 2008.

instead indicates information about the social interaction the speaker is having.

Understanding register requires one to appreciate these social interactions, as well as the linguistic devices that are used to signal them. Registers are marked through a variety of linguistic elements. For example, infant-directed (ID) speech involves characteristic changes in pitch (Fernald, 1992), lexical items (e.g., ''goo goo''), and syntactic complexity (Newport, Gleitman, & Gleitman, 1977). Similarly, formal polite speech involves special lexical items (words like ''please'' and ''thank you''), syntactic constructions (Ervin-Tripp, 1977) and in some languages, pronoun choices (Brown, 1996). The specific lexical and syntactic elements used to signal different registers vary from language to language (Brown, 1996; Nakamura, 2001) and children must learn the mapping between linguistic elements and social situations. Moreover, there is also some variation in which social situations warrant distinctive registers (see e.g., Nakamura, 2001), so children must also learn their cultural norms to fully master this dimension of language use.

Previous work looking at children's ability to shift their own style of speech as a function of social context suggests that seeds of this ability may be present quite early: Weeks (1971) found that even a 1-year-old would shift his speech to reflect the social environment (e.g., indoor vs. outdoor speech). However, it is not until about age 4 years that children seem to command registers roughly parallel to those in the adult language. In a pioneering study, Shatz and Gelman (1973) found that 4-year-olds talk differently (e.g., using shorter, less complex utterances) to younger children than they do to either peers or adults. Moreover, in her extensive production studies, Andersen found that starting around age 4 years, children can shift their speaking style in response to a variety of social factors (Andersen, 1992, 1996; Andersen, Brizuela, DePuy, & Gonnerman, 1999). In these studies, children were given various puppets and asked to provide their voices in different situations. Children demonstrated sophisticated knowledge about the range of ways that language reflects social status. For example, when speaking for the doctor puppet, children used more imperative commands and asked fewer questions than when speaking for the nurse puppet. Similarly, children adjusted the choice of lexical items (using terms like ''sweetie'' more when speaking as the mommy puppet), the pitch of the utterance (using a deeper voice when speaking as the daddy puppet), and the use of discourse markers designed to help a speaker keep their turn in the conversation (they held their turn more aggressively when speaking as the doctor and teacher puppets).

Other researchers have similarly found that by age 4 years, children can shift their speech register to be more polite (James, 1978), and more impressively, to facilitate actual interpersonal interactions (Ervin-Tripp, 1977; Kyratzis, Marx, & Wade, 2001). However, children's skill at shifting registers improves dramatically with age. In Andersen's studies (Andersen, 1992, 1996; Andersen et al., 1999), the 6-year-olds were far more consistent about changing their speaking style and did so over a broader range of social contexts. Other researchers have also found that children improve their control of register throughout childhood. For example, children develop in their ability to ask ''nicely'' when requesting a desirable object from an older adult (Bates & Silvern, 1977; Nippold, Leonard, & Anastopoulos, 1982) and do not command the subtleties of polite speech until late in the grade school years (Pedlow, Sanson, & Wales, 2004; Pedlow, Wales, & Sanson, 2001). Children's comprehension of polite speech shows a similar developmental trajectory (Baroni & Axia, 1989; Bates & Silvern, 1977; Bernicot & Legros, 1987; Nippold et al., 1982; Pedlow et al., 2001; Pedlow et al., 2004).

This study expands on previous research in two critical ways. First and foremost, this study focuses on the intrinsic flexibility at the core of register: The very same individual should command multiple registers and deploy them appropriately depending on their listener. Previous experimental studies have examined only a single register at a time and therefore cannot speak to children's appreciation of how a single speaker shifts speech styles. This study tested children with three different registers, each associated with social interactions that should be reasonably familiar to children: formal polite speech (as a child might use to a teacher), casual speech (as a child would use to a peer), and ID speech (as one would speak to a baby). Second, this study focuses on children's comprehension as opposed to their production abilities. As noted previously, appropriate production of registers requires facility with a full range of linguistic levels and children may well understand the import of registers before they can produce an adult-like example of one. Indeed, recent work suggests that before 2 years of age, children can extract a great deal of information from speech not directly addressed to them, including detecting differences in fluency (Soderstrom & Morgan, 2007) and even learning the meanings of words (Akhtar, Jipson, &

Callanan, 2001; Floor & Akhtar, 2006). Similarly, children may be able to extract register information and use it despite limited command in their own production.

In addition, to provide a baseline of ability in this task, we tested children with a foreign language (Spanish). Hirschfeld and Gelman (1997) found that by age 4 years children associate people who speak a foreign language with foreign objects (e.g., non-Western housing and clothing). Linking a foreign language to someone from far away is conceptually similar to linking a particular register with the right social partner; in both cases, one needs to know that the language is providing information about the social identity of the listener. However, as even newborns can discriminate among different languages (Mehler et al., 1988), it was expected that the linguistic features of Spanish would be easy for children to detect and use.

In our task, children were asked to identify who a speaker was addressing based on her choice of register. In addition, for half the trials, we asked children to justify their responses. This additional task was added in an exploratory spirit to see if children's success with register was linked to their metalinguistic understanding of it. The motivation for this task came from the field of bilingualism. For bilingual speakers, the language they speak (e.g., French vs. Spanish) is not stable but instead, like register, switches flexibly depending on the social situation. Bilingual children tend to be quite sophisticated at understanding how social situations should guide their language choices (Petitto, Katerelos, Levy, & Tétreault, 2001) and they are ahead of their monolingual peers on some metalinguistic tasks (Bialystok, 2001; Jessner, 2006). Moreover, Jordá (2003) found that bilingual adults were better than monolinguals at providing relevant justifications for their performance on a linguistic task. To the extent that both register and bilingualism require one to choose among one's repertoire of speech styles to match a social situation, we might find a similar link between metalinguistic skill and register understanding.

Method

Participants

Participants were 56 children, divided into three groups: 3-year-olds ($n = 18$, $M = 42.2$ months), 4-year-olds ($n = 20$, $M = 55.5$ months), and 5-year-olds ($n = 18$, $M = 68.3$ months). Approximately half the children in each group were girls. The data from an additional 10 children were excluded because of equipment failure or experimenter error (5 children) or because the children failed to pass the pointing task described in the Procedures section (5 children, mean age = 46 months). All children were monolingual speakers of English from a large American Midwestern city; most of the children were Caucasian and were from a mid to high socioeconomic status. All were recruited by telephone and were tested in a university laboratory setting.

Stimuli

A frog puppet was the nominal speaker of all sentences. Neither the sex nor the age of the puppet was specified, and it spoke with the voice of a college-aged woman (the second author). All sentences were prerecorded and played as QuickTime files on a laptop computer.

The same four linguistic tokens were used throughout; each began with an attention-getting introduction and then asked for a person's name. Inquiring after names was chosen because pilot testing found that children accepted it as a plausible question to ask a variety of people, including infants. The tokens varied with respect to speech style and differed at many linguistic levels, including prosody, phonology, lexical choices, and syntax. Transcripts of the tokens can be found in Table 1. The ID token was spoken in a high-pitched voice with large pitch excursions; this special prosodic contour was particularly pronounced in the attention-getting word (''Awwww''). Syntactically, the ID token used an indirect question. The *formal* speech token used explicit politeness terms (''Excuse me,'' ''Please''), an indirect question in a modal verb construction (''can'') and did not contract across words phonologically. The *casual* token used an informal attention-getter (''Hey''), a simple question construction, and contracted the auxiliary verb. The *Spanish* token was spoken in a casual register in Spanish.

The target addressee for the ID speech was a picture of an infant; for the casual speech, a blonde toddler girl; for the formal speech, an adult woman; and for Spanish, a dark-haired toddler girl. Note that all the pictures (except those of the infants) depicted females. Thus, gender could not be used in the study to differentiate among the choices. The pictures were all presented on 8 in. × 6 in. laminated cards. There were three exemplars of each picture type used in the study. One example of each type is shown in Table 1.

Table 1
Linguistic and Visual Stimuli Used

Test register	Linguistic stimuli	Target picture	Target picture choice (1 example of 3 used)
Infant directed speech	*Awwww, I wonder what your name is?*	Baby	
Casual speech	*Hey, what's your name?*	Little girl who lives nearby	
Formal speech	*Excuse me please, can you tell me your name?*	Teacher	
Spanish	*Hola! Como se llamas?*	Little girl who lives far away	

Procedure

To insure that children were familiar with all the target pictures and could classify them appropriately, participants began by identifying the person in all 12 of the target pictures (3 of each target type) and sorting them into the four target groups. To ensure that children distinguished between the two kinds of little girls, the first example of each of these types was presented with a special introduction. For the little blonde girl, children were told: "This little girl lives right here in town. She lives very close by." For the little dark-haired girl, children were told: "This little girl lives very far away. She lives in a completely different country." Feedback was given during the sorting, and children were encouraged to use our labels for the pictures (baby, teacher, little girl who lives far away, little girl who lives nearby). These descriptions were repeated as needed throughout the sorting session. Following the sort, children were asked to point in a pseudo-random order to six pictures to insure that they could identify all the types. Children who failed to get 100% correct at this pointing task were excluded from analysis.

Children were then introduced to the frog puppet who wanted to meet new people and were asked to tell the frog their own name. They were told that the frog would meet some of the people in the pictures and were instructed to listen to the frog and say who she was talking to. For each test trial, children saw a pair of pictures: a target (the correct answer) and a foil. The foil pictures were all targets for different registers. The linguistic stimulus was played and the child was asked: "Who was she talking to?" Each type of target was tested three times, once paired with each of the possible foil picture types, for a total of 12 test trials. Children's responses consisted of selecting one of the two pictures. On the last six trials, children were also asked to justify their choices.

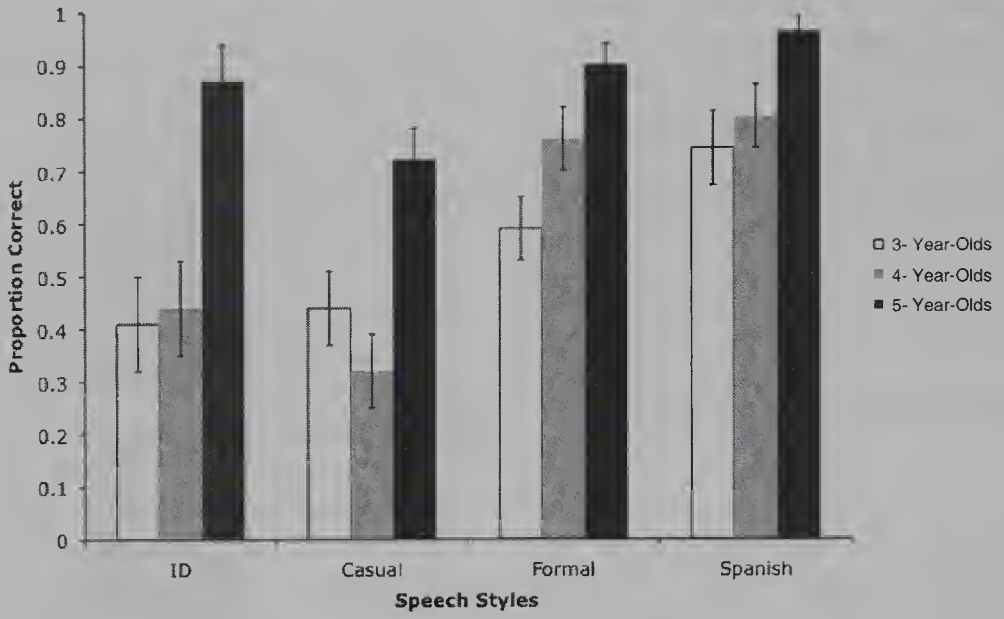

Figure 1. Mean correct responses by speech style and age.
Note. ID = infant directed.

Results

An analysis of variance (ANOVA) was conducted on the proportion correct with age as a between-subjects factor (3-, 4-, and 5-year-olds) and speech style as a within-subjects factor (ID, casual, formal, Spanish). The analysis found a main effect for age, $F(2, 53) = 24.3$, $p < .001$, $\eta^2 = .48$. Post hoc comparisons (Tukey's honestly significant difference [HSD], $p < .05$) found that 5-year-olds did significantly better than 4-year-olds who in turn did significantly better than 3-year-olds. A main effect was also found for speech style, $F(3, 51) = 9.5$, $p < .001$, $\eta^2 = .15$. Post hoc paired t tests (all ps < .05) found that children did significantly better with Spanish than all other speech styles, they did significantly better with the formal register than with the other two styles, and they did equally well with the casual register and the ID register. There was no significant interaction between age and speech style. The means for all registers by age group are shown in Figure 1.

To assess children's objective level of ability with each speech style, we compared their performance to chance (.50). The 5-year-olds were significantly above chance with all four speech styles: Spanish, $t(17) = 18.2$, $p < .001$, $d = 8.8$; formal, $t(17) = 11.2$, $p < .001$, $d = 5.4$; casual, $t(17) = 3.6$), $p < .01$, $d = 1.7$; and ID, $t(17) = 5.5$, $p < .001$, $d = 2.7$. Moreover, the number of 5-year-olds scoring at least .67 correct for all four speech styles was significantly above chance by a binomial test (17/18, $p < .001$); even for the hardest style (casual speech), a significant number of 5-year-olds were above chance (14/18, $p = .031$). The 4-year-olds were significantly above chance with Spanish, $t(19) = 5.3$, $p < .001$, $d = 2.4$ and the formal register, $t(19) = 4.2$, $p < .001$, $d = 1.9$, but performed at chance with the casual register, $t(19) = 0.74$, *ns*, and the ID register, $t(19) = 1.88$, *ns*. The subjects analysis confirmed that a significant number of participants performed above chance with Spanish and the formal register (in both cases, 17/20, $p = .003$ by binomial test), but not for ID speech (12/20, $p > .5$ by binomial test). However, despite the fact that the overall score was not above chance for the casual register, a significant number of 4-year-olds did score at least .67 correct with it (15/20, $p = .041$ by binomial test). Finally, the 3-year-olds scored no better than chance with the formal, casual, and ID registers (all ps > .1) but did score above chance with Spanish, $t(17) = 3.5$, $p = .003$, $d = 1.7$. However, the subjects analysis revealed that for none of the speech styles did a significant number of participants score above .67, not even for Spanish (13/18, $p = .096$ by binomial test). We were surprised at how poorly the children performed with ID speech and checked to see if children with more exposure to the use of ID speech—for example, children with younger siblings—would better understand its use. We compared the performance with ID speech of participants with and without younger siblings, but there was no difference between these groups, $F(1, 53) = 0.53$, $p > .4$. Raw exposure to ID speech directed to others did not determine success in understanding it.

Inspection of the data revealed that there were base-rate effects for choosing different types of

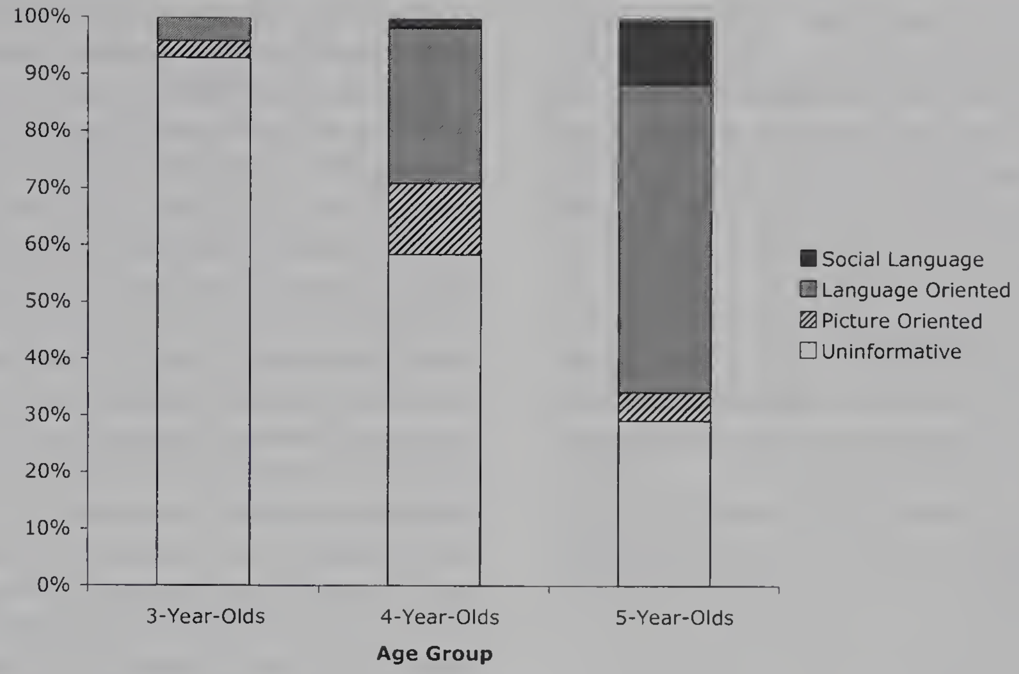

Figure 2. Percentage of the different justifications used.

pictures. In particular, 3- and 4-year-olds avoided choosing pictures of babies and were positively disposed to choose pictures of the girls who lived far away. The chance comparisons just noted may therefore have underestimated children's ability with ID speech (where the baby pictures were the correct targets) and overestimated their ability with Spanish (where the pictures of the girl who lived far away were the correct targets). Therefore, the chance analyses were redone with chance corrected to the actual base-rate for choosing the target (i.e., the average rate at which the target was chosen across the entire experiment). For the 5-year-olds, the base rates varied between .44 and .56 across targets, and the new analyses were qualitatively identical to the standard chance analysis. For the 4-year-olds, the base rates varied between .33 (for the baby pictures) and .63 (for the girls who lived far away). The corrected chance analyses yielded qualitatively identical results except for the case of ID speech: Four-year-olds did choose the picture of the baby significantly more frequently than their base rate preference, $t(19) = 2.2$, $p = .039$, $d = 1.0$. For the 3-year-olds, the base rates varied between .38 (for the baby pictures) and .66 (for the girls who lived far away). The corrected chance analyses also yielded qualitatively identical results except for the case of Spanish: Three-year-olds failed to choose the correct target more than their base rate preference, $t(17) = 1.2$, $p > .2$. One additional analysis (suggested by a reviewer) looked at whether the 3-year-olds could successfully contrast Spanish and the casual register just in those cases where the pictures contrasted the two kinds of little girls. The results found that they were equally likely to choose the little girl who lived far away with both those speech styles, $t(17) = 0.6$, *ns*, reinforcing the base-rate-corrected analysis that these children do not succeed with Spanish.

Finally, we analyzed children's justifications of their choices. Children's responses were classified into one of four categories. The first category was uninformative and was composed of justifications such as "I don't know" and "just because." The language-oriented category was broadly construed and included any answer making any reference to the linguistic stimuli, no matter how vague ("That's what it sounded like," "Because she had a pretty voice," "Because she said awwww"). It also included justifications that simply identified the stimuli as being Spanish ("Because she's speaking Spanish"). The picture-oriented category was used for references to the people in the pictures with no mention of language: "Because she had the same color hair as me," "Because she's from far away," Last, the social-language category consisted of answers that expressed an understanding of how the language was being tailored to the social category of the people in the pictures; for example, one child justified choosing the little girl who lives nearby after hearing the casual register by saying "because people say 'hi' to kids."

The distribution of the justifications is shown in Figure 2. The 3-year-olds' justifications were almost always uninformative (94.4%), which stands in marked contrast to the older children's justifications. One-way ANOVA comparisons between the 4- and 5-year-olds' justifications showed that the older children gave significantly fewer uninformative justifications, $F(1, 37) = 6.3$, $p = .017$, $\eta^2 = .15$, and significantly more language-oriented justifications, $F(1, 37) = 6.7$, $p = .014$, $\eta^2 = .16$, as well as social-language justifications, $F(1, 37) = 4.7$, $p = .036$, $\eta^2 = .12$. Moreover, children who gave better justifications also did better on the task as a whole. Looking just at the 4- and 5-year-old children (i.e., children who gave a range of justification types), a Pearson's correlation found a significant negative relation between children's overall proportion correct on the task and the proportion of uninformative justifications that they gave ($r = -.48$, $n = 38$, $p = .002$). That is, as children did better on this task, they were more likely to offer a reasonable justification for their choices.

Discussion

This study investigated children's developing ability to understand the social implications of using a particular register: Can a child tell who someone is speaking to based on the style in which they choose to talk? The results show that there is a dramatic improvement in children's ability to interpret register information around the age of 4 years and that this ability is broad based, applying flexibly to many different registers from a single speaker. Understanding of register continues to improve with age, and 5-year-olds are much more facile in their understanding. Moreover, these older children also have an improved appreciation of the basis of that understanding and provide substantially better justifications for their responses. These results suggest that there may be a connection between being flexible with register understanding and being able to explicitly think about language itself.

These results go beyond recent findings of Kinzler and colleagues (Kinzler et al., 2007; Kinzler et al., 2009) about children's ability to link linguistic and social information. Kinzler and colleagues found that preschool-age children can use the language of a speaker as a stable indicator of their social desirability; by contrast, these results show that by age 4 years, children also understand that speakers can shift their style of speaking depending on their conversational partner. Children's success with register suggests that they understand not only how language can stand proxy for stable social categories but also how language can be used to respond to different social partners. Moreover, the fact that children succeed with multiple registers shows that they understand the inherent flexibility of register; a speaker's social partners are subject to change and so are a speaker's registers.

The age of children's success was not notably different from what has been found in production studies (Andersen, 1992; James, 1978; Kyratzis et al., 2001; Shatz & Gelman, 1973), suggesting that children's comprehension of register is tied to their earliest successful attempts to produce it. What is notable about these results is the fact that the children succeeded despite the fact that they were essentially eavesdropping on other people's conversations. Akhtar and colleagues (Akhtar et al., 2001; Floor & Akhtar, 2006) have previously shown that children can listen in on adult conversations to learn the meanings of words, but the children in this study were extracting social linguistic information far beyond word meanings. Despite having no social position in the conversation of their own, the children were nevertheless identifying critical social characteristics of the participants (e.g., being a peer vs. being an adult) as well as social characteristics of the language being used (e.g., ID speech vs. formal speech). Children's success even as third-party observers shows how salient language is as a social marker (it is one that does not even require personal engagement); moreover, it points to a potential path for acquisition. Rogoff, Paradise, Arauz, Correa-Chávez, and Angelillo (2003) discuss the importance of eavesdropping—or what they call ''listening in''—in children's acquisition of a variety of skills cross-culturally. Interestingly, they argue that a critical feature to this process is that children anticipate that they will themselves eventually be asked to engage in the activity which they are listening in on. If this argument is correct, it implies that children may in fact anticipate the need to modulate their own speech style for different social settings before they themselves have direct need of it.

Finally, this study suggests that there is a positive link between children's ability in the comprehension task and their metalinguistic appreciation of the speech styles involved, as measured by their justifications. An examination of the differential success among the speech styles further supports the idea that the two are connected. For example, Spanish was the easiest style for children to link to a social category, and it was also the style for which children did the best job of justifying their choices: A full 47.9% of the language-oriented justifications made reference to the Spanish language in some way. No other speech styles were mentioned so explicitly in the justifications; however, a comparison between the formal and casual registers further suggests a role for explicit knowledge.

Children performed far better with the formal register than the casual one: Four-year-olds succeeded robustly with the former, but only marginally with the latter (although a significant number of 4-year-olds did comprehend this register successfully, children did not succeed as a group until age 5 years). The formal register was distinguished by its inclusion of polite terms such as "please" and "excuse me." Previous research suggests that in naturalistic settings, parents explicitly encourage their children to use these particular words when speaking to adults (Becker, 1994; Gleason, Perlmann, & Greif, 1984), and they appear to serve as critical markers of polite speech for children as old as 10 years (Pedlow et al., 2001). By contrast, the casual register was largely defined by what it lacked: It was normal, neutral speech with no distinctive intonational patterns or lexical items. The differential success of these two registers suggests that children may require specific, familiar linguistic markers to categorize the speech and connect it to their social understanding. If this suggestion is correct, it predicts that children may find it easier to understand register distinctions in languages which have specific grammatical elements associated with them (such as the way pronoun choice signals casual vs. formal speech in many Romance languages).

In both these cases, of course, the data is only correlational, and it is unclear whether children's facility with the speech styles is driving improvements in their metalinguistic abilities (presumably the direction of causation for bilingual children) or whether independent improvements in metalinguistic ability are helping them better comprehend speech registers. Further studies will be needed to determine if there is a strong parallel between knowing multiple languages and knowing multiple registers, or if the two are linked to improved metalinguistic understanding for different reasons.

Altogether, these results suggest that around age 4 years, children develop an appreciation for register and linguistic style that extends beyond their own social interactions. They understand that individual speakers can flexibly shift their speaking style as a function of their conversational partner; moreover, they understand which specific registers in their native language should be used with different social partners. Children's success reflects, on the one hand, a language specific ability, namely, the particular way that English signals formal, casual, and ID registers. The fact that there are some differences in how well children perform with these different registers speaks to the very English-specific knowledge that children must acquire. On the other hand, the fact that children succeed with multiple registers at once suggests that they have grasped the general principle underlying register use, namely, that language can be used to signal a social relationship between conversational partners.

Goal Neglect and Working Memory Capacity in 4- to 6-Year-Old Children

Stuart Marcovitch and
Janet J. Boseovski
University of North Carolina at Greensboro

Robin J. Knapp
University of Miami

Michael J. Kane
University of North Carolina at Greensboro

Goal neglect is the phenomenon of failing to execute the momentary demands of a task despite understanding and being able to recall the task instructions. Successful goal maintenance is more likely to occur in adults with high working memory capacity (WMC) who can keep rules mentally accessible while performing the task. The current study predicted that goal neglect would also be related to WMC in children. It assessed thirty-seven 4-year-old and twenty-eight 6-year-old children on the goal neglect version of the Dimensional Change Card Sort, and 3 tasks that measure WMC. As predicted, children with higher WMC scores were more likely to maintain goals adequately for task performance. The findings are consistent with a 2-factor model of working memory and its development.

Goal-directed behavior is complex, as it necessitates a representation of the goal state, formulation of a plan to achieve the goal state, and the ability to hold the goal in mind so that it may guide behavior at the appropriate time. Failure to behave accordingly, despite demonstrating knowledge of the appropriate actions, has been termed ''goal neglect'' (Duncan, Emslie, Williams, Johnson, & Freer, 1996) and has often been attributed to momentary lapses in working memory in typically developing populations (Kane & Engle, 2003) and associated with fluid intelligence and frontal lobe functioning (Duncan, 1995). Importantly, goal maintenance relies on self-regulatory skills such as persistence and resistance to distractibility, which are known to predict school readiness and academic success (Blair, 2002; McClelland et al., 2007).

We take the view that goal neglect can result in perseverative responding, the tendency to behave incorrectly in a manner that was previously correct. Perseverative responding is seen widely in infancy and early childhood and may result from the inability to maintain the goal representation sufficiently to override a prepotent response (Marcovitch & Zelazo, 2009). This view is consistent with a number of theories of goal-directed behavior in children, and we will illustrate its potency by examining theories of performance on the Dimensional Change Card Sorting task (DCCS; Zelazo, Frye, & Rapus, 1996; Zelazo, Müller, Frye, & Marcovitch, 2003), a popular measure of executive function in young children. In the DCCS, children are told an explicit rule to match cards according to one dimension (e.g., color). After several trials, the rule is changed so that the children now match cards by the other dimension (e.g., shape). For example, children may be instructed to match blue circles and green squares to a blue square and a green circle. They initially are instructed to sort by color, thus matching blue circles to the blue square and green squares to the green circle. After a number of trials, the rule is switched and they are instructed to sort by shape, thus matching blue circles to the green circle and green squares to the blue square. Although 3-year-olds can sort the cards by each rule independently, they have difficulty following the second rule after sorting by the first. Of importance, despite sorting incorrectly after hearing the second rule, children display knowledge of the rule when asked to point to the correct location (Zelazo

et al., 1996), when judging the sorting behavior of a puppet (Jacques, Zelazo, Kirkham, & Semcesen, 1999), and when told to verbalize it (Kirkham, Cruess, & Diamond, 2003; Towse, Redbond, Houston-Price, & Cook, 2000; but see Müller, Zelazo, Lurye, & Liebermann, 2008). Thus, the criterion for goal neglect set forth by Duncan (1995) is met—children know the appropriate response but do not execute it.

Although there are several disparate accounts of perseveration in the DCCS, they all (explicitly or implicitly) share the central feature that children who perseverate are not holding the correct rule in mind. In the revised version of cognitive complexity and control theory, Zelazo et al. (2003) argue that increases in levels of reflection allow for the formation and implementation of higher order rules that are needed to handle the two contradistinctive rules simultaneously. Children who do not formulate, and thus cannot hold in mind, higher order rules have difficulty on the DCCS. In contrast, children who succeed on the task not only know the rules, but they know that they know the rules allowing them to consider the contradistinctive rules in parallel. According to a different account of perseveration, the attentional inertia account (Kirkham et al., 2003), children perseverate by continuing to act on the wrong rule unless they are primed to activate the correct rule by emphasizing the relevant dimension such as through labeling. Thus, success hinges on accessing the appropriate rule as needed. Similarly, in redescription accounts of the DCCS (Kloo & Perner, 2005; Perner & Lang, 2002), young children cannot think about a stimulus as two things simultaneously (i.e., a *red* thing and a balloon) and therefore it is difficult for them to maintain the new rule in mind, which requires redescribing the stimulus after the rules have been switched. Finally, in accounts that link perseveration to the degree of conflict (Jordan & Morton, 2008; Morton & Munakata, 2002), children's performance can be improved when the degree of conflict is degraded by increasing the salience of the postswitch dimension and the likelihood that the rule is kept in mind. Thus, all the primary accounts of the DCCS attribute perseveration to a failure in accessing the correct rule, which is a central tenet of goal neglect.

Towse, Lewis, and Knowles (2007) investigated goal neglect and its potential causes in young children by combining elements of the DCCS procedure with those of Duncan's (1995) method of inducing goal neglect in adults. Here, 4-year-old children were presented with the outlines of a blue house (on the left) and a red house (on the right) on a laptop computer, and were explained that food items would appear in the houses, but that they should only focus on one particular house. They were taught the rules of the game: (a) On the first presentation of the food items, an arrow will point to the target house that children should initially attend and name the food items. (b) At some unpredictable time, a new task signal will appear: If it is a blue square, then children should begin to name the items in the blue house, but if it is a red square, they should begin to name the items in the red house. Note that these signals sometimes cued the children to continue with the same house, and sometimes required them to switch houses. Because children were tested on whether they understood the rules prior to the study, failure to switch houses after the presentation of the appropriate cue was considered goal neglect. Interestingly, this type of goal neglect correlated negatively with performance on the DCCS, suggesting that goal maintenance is directly related to task switching.

The DCCS has also been modified to assess goal neglect in 4- and 5-year-olds, who typically perform well on the DCCS (Marcovitch, Boseovski, & Knapp, 2007). In the goal-neglect version of the DCCS (GN–DCCS), children received five preswitch trials where they were instructed to sort according to one dimension (e.g., color). On the postswitch trials, children received 30 trials where they were instructed to sort according to the other dimension (e.g., shape). Two types of stimulus cards were used in the postswitch: *conflict* cards, which were the standard DCCS cards where one dimension mapped on to one target card while the other dimension mapped onto the other target card, and *redundant* cards, which were identical to the target cards (see Figure 1). In the *mostly conflict* condition, 80% of the postswitch trials were conflict cards. In contrast, in the *mostly redundant* condition, only 20% of the postswitch trials were conflict cards (i.e., the preponderance of cards were redundant). Marcovitch et al. (2007) reasoned that in the context of constantly sorting conflict cards, it would be relatively simple to keep the relevant postswitch rule in mind either because the conflict trials reinforce the sorting rule, or because the presence of repeated conflict reinforces the need to keep the rule in mind. On the other hand, in the context of constantly sorting redundant cards—where theoretically no rule is needed most of the time, as the test card matches one of the targets on both dimensions—it is more challenging to recall the correct rule when finally faced with a conflict card. Thus,

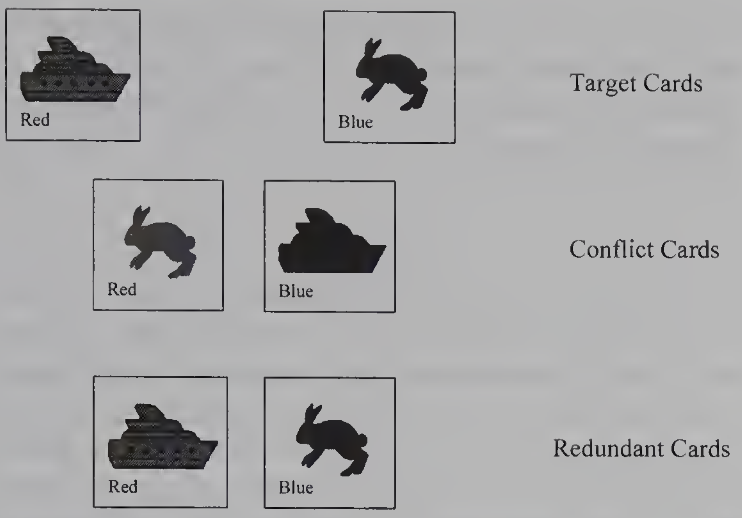

Figure 1. Sample target, conflict, and redundant cards used in the study.
Source: Reproduced from Marcovitch et al. (2007).

Marcovitch et al. predicted that a higher percentage of conflict cards will be sorted correctly in the mostly conflict condition as compared with the mostly redundant condition, which they considered the measure of goal neglect. This is precisely what was found, regardless of whether the children were reminded of the rule once (Experiment 1) or before every postswitch trial (Experiment 2). The latter provides a striking example of goal neglect given that children were told the correct rule immediately prior to sorting each and every card.

In their Stroop study with adults, Kane and Engle (2003) found that performance in a mostly redundant condition (i.e., with most color words presented in their matching hues) was related to individual differences in working memory capacity (WMC). From Kane and Engle's perspective (see also Engle, 2002; Engle & Kane, 2004), WMC reflects "the interaction of attentional and memorial processes in the working memory system, and . . . this interaction between attention and memory is an elementary determinant of broad cognitive ability" (Engle & Kane, 2004, p. 147). Furthermore, they contend that individual differences in WMC are attributed primarily to differences in the control of actively maintaining goal-relevant information. Thus, individuals with high WMC are more likely to maintain a goal actively in the face of distraction, even across extended periods of time where goal activation is only occasionally (and unpredictably) necessary.

Following this perspective, Marcovitch et al. (2007) argued that, compared with adults, 4- and 5-year-old children have difficulty in maintaining goals and that this was the predominant factor for their poor performance on the mostly redundant sort. However, Marcovitch et al. were interested in group performance and did not assess WMC in the children. In the current study, we assessed individual differences in WMC in 4- to 6-year-old children to determine whether WMC was related to goal neglect as measured by the mostly redundant sort. We assessed WMC via three working memory span tasks that all require keeping in mind a series of items while intermittently performing an unrelated, secondary task (e.g., Case, Kurland, & Goldberg, 1982). Given the importance of maintaining representations over time and in the face of distraction on these tasks, we hypothesized that if the mostly redundant card sort indeed relied on these skills then performance should be predicted by individual differences in WMC. Alternatively, it is entirely possible, and consistent with Marcovitch et al.'s (2007) earlier findings, that young children as a whole may not yet have the necessary capacity to maintain goals across periods of inactivity. In other words, even if children's WMC is high relative to their peers, the absolute level of WMC may still not be sufficient to succeed on the mostly redundant sort.

Establishing that individual differences in WMC impact performance on the mostly redundant sort is theoretically and practically important, for several reasons:

1. It would provide a unified explanation for goal neglect from early childhood to adulthood. We hypothesize that goal neglect is a byproduct of the inability to maintain a representation over time and distraction, a skill measured directly by working memory span tasks.
2. A positive relation would imply that improvements in WMC—perhaps via special training—would also improve goal maintenance (e.g., Klingberg et al., 2005). This may be extremely useful for improving goal-directed behavior in typical populations in educational settings, as well as atypical populations in directed training sessions.

We further hypothesize that WMC should be related to performance on the mostly conflict sort for the younger but not the older children. This is because goal maintenance is still required to pass the mostly conflict sort, but the constant usage of the rule makes it easier to keep in mind and partially scaffold performance for the younger children with lower WMC. Older children will generally not require the additional scaffolding to succeed on the mostly conflict sort, and thus no relation between WMC and performance is expected.

Finally, we wanted to assess to what degree WMC predicts performance on each card sort above and beyond the other card sort. On one hand, we expect a meaningful amount of variance common to both card sorts to be accounted for by WMC, as both card sorts have many procedural similarities, and both require goal maintenance albeit to different degrees. However, consistent with the two-factor theory of executive control postulated by Engle and Kane (2004; for a related view, see Braver, Gray, & Burgess, 2007), we also predict that WMC may account for unique variability in the performance of each card sort. According to Engle and Kane, one factor of executive control is "the maintenance of the task goals in active memory" (p. 186), potentially assessed in the current study by performance on the mostly redundant card sort. Engle and Kane argue that goal maintenance is resource-demanding, and thus better executed by individuals with high WMC. The other factor of control is "the resolution of response competition or conflict, particularly when prepotent or habitual behaviors conflict with behaviors appropriate to the current task goal" (p. 186), potentially assessed in the current study by performance on the mostly conflict sort. If each card sort is a measure as a distinct factor of WMC, then variability in performance for each sort should be accounted for uniquely by our measures of working memory.

Method

Participants

We recruited children in a midsized Southeastern city from local day care centers and from a database of parents who had previously expressed interest in participating in research studies. There was no payment for participation, although the children received a gift after the study. The treatment of participants was in accordance with the ethical standards of the American Psychological Association and the study was approved by the local Institutional Review Board. The final sample consisted of thirty-seven 4-year-olds (*M* = 4.71 years, range = 4.02–5.45, 16 girls) and twenty-eight 6-year-olds (*M* = 6.22 years, range = 5.55–6.98, 15 girls). Thirteen additional children (ten 4-year-olds and three 6-year-olds) were tested but their data were not included because they did not perform to criterion on the preswitch sorts (see the following). The sample was racially diverse (69% self-reported as White, 18% Black, 3% biracial, 3% Asian, and 8% preferred not to respond) with varying levels of socioeconomic status (51% reported household earnings over $60,000, 26% under $60,000, and 23% refused to respond).

Materials

For the GN–DCCS, laminated cards (13 cm × 8 cm) depicted either a yellow car, a yellow flower, a green car, a green flower, a red boat, a red bunny, a blue boat, or a blue bunny (all pictures were approximately 16 cm × 16 cm). Participants sorted the cards into two gray sorting boxes (28.5 cm × 20 cm × 11 cm) with slits that had been cut into the lids.

In the Visual Counting Span task of WMC, two types of stickers were affixed to paper cards (21 cm × 20 cm): hearts and American flags, stars and rainbows, or bees and frogs. The number of stickers of each type per card ranged from one to eight. In the Visual Backward Word Span task, paper cards (14 cm × 14 cm) depicted a picture of a common object or animal (approximately 5 cm × 4 cm). Finally, in the Auditory Backward Digit Span task, we presented stimuli using a stuffed pink and white rabbit toy named "Fluffy."

Design and Procedure

In the experimental session, all children completed the three WMC tasks (Visual Counting Span, Visual Backward Word Span, and Auditory Backward Digit Span) and the two card sorting tasks (mostly redundant, mostly conflict). The order of the tasks was counterbalanced with the constraint that the first, third, and fifth tasks were WMC tasks whereas the second and fourth tasks were card sorting tasks.

Goal-Neglect DCCS

All children participated in two games: one *mostly redundant* card sort and one *mostly conflict* card sort (Marcovitch et al., 2007). Children sorted red and blue bunnies and boats in one game and yellow and green cars and flowers in the other. At the beginning of each game, the experimenter affixed the target cards—which differed by both color and shape (e.g., red boat and blue bunny; see Figure 1)—to the sorting boxes. In the five preswitch trials, children were instructed to sort test cards according to one dimension (e.g., color) that was counterbalanced across task order: "In the ________ (shape/color) game, _______ (bunnies/red ones) go here [pointing to the box with the red bunny] and ________ (boats/blue ones) go here [pointing to the box with the blue boat].'' Note that for preswitch trials, all test cards were conflict cards (i.e., the same color as one target, but the same shape as the other target) and the instructions were repeated before every trial. As it is critical for the logic of the task that children pass the preswitch phase, only children who sorted correctly on at least 8 of 10 preswitch trials across both tasks were included in the final sample (see Marcovitch et al., 2007).

On the postswitch trials, the instructions were changed so that children were now required to sort by the other dimension (e.g., shape). Children then received 30 postswitch trials such that the rule was repeated before every fifth trial, regardless of whether it was a redundant or conflict trial. When playing the mostly conflict game, the first 6 trials, and 18 of the remaining 24 trials involved conflict cards (i.e., 80% of all postswitch trials used conflict cards). The remaining 6 trials used redundant cards which matched one of the targets exactly. When playing the mostly redundant game, the contingency was reversed (i.e., 80% of all postswitch trials used redundant cards). In both sorts, the placement of the conflict and redundant cards were randomized for each participant.

Working Memory Tasks

Visual Counting Span (Case et al., 1982). In this task, children were shown cards, one at a time, which displayed pictures of two objects (e.g., frogs and balloons). They were instructed to count one of the objects (e.g., balloons) and remember the number before turning the card face down, after which they were required to recall the numbers in the correct order. Children received three sets each of 2 cards, 3 cards, 4 cards, and 5 cards, in that order.

Visual Backward Word Span (Carlson, Moses, & Breton, 2002). In this task, children were shown cards, one at a time, each of which displayed a single picture familiar to young children (e.g., car, tree, and shoe). The children were asked to identify each picture aloud before turning the card over and then to recall the items in reverse order. Children received three sets each of 2 cards, 3 cards, 4 cards, and 5 cards, in that order.

Auditory Backward Digit Span (Carlson et al., 2002). Children were shown and told about Fluffy, the silly bunny puppet who says things backward. After speaking a list of numbers, the experimenter asked, ''Fluffy says things backwards, so what would he say?'' Children heard three sets each of 2 numbers, 3 numbers, and 4 numbers, in that order.

Results

For all analyses, α is set to .05 for statistical significance and .10 for marginal significance.

Goal-Neglect DCCS

The proportion of conflict cards sorted correctly in each sort is displayed in Figure 2. A 2 × 2 (AGE GROUP × SORT TYPE) mixed analysis of variance (ANOVA) with SORT TYPE as the repeated measure revealed an effect of SORT TYPE, $F(1, 63) = 7.1$, $p < .01$, $MSE = 0.051$, $\eta_p^2 = .10$, such that children sorted more conflict cards correctly in the mostly conflict condition. This replicated the previous finding of goal neglect (Marcovitch et al., 2007). The ANOVA did not reveal an effect of AGE GROUP, $F(1, 63) = 2.0$, $p > .10$, $MSE = 0.11$, $\eta_p^2 = .03$, nor an interaction between AGE GROUP and SORT TYPE, $F < 1$, $MSE = 0.051$, $\eta_p^2 = .00019$.

We also analyzed whether the presentation order of the card sort (ORDER) had an effect on performance, and whether it interacted with AGE GROUP and SORT TYPE. We did find an effect of ORDER, $F(1, 61) = 8.2$, $p < .01$, $MSE = 0.097$, $\eta_p^2 = .12$, such that children who received the mostly redundant card sort first performed better on both card sorts. Notably, there was no interaction between ORDER and AGE GROUP, $F(1, 61) = 1.9$, $p > .10$, $MSE = 0.097$, $\eta_p^2 = .03$, nor between ORDER and SORT TYPE, $F < 1$, $MSE = 0.052$, $\eta_p^2 = .00$, which demonstrates that the effect of goal neglect holds regardless of the order of presentation.

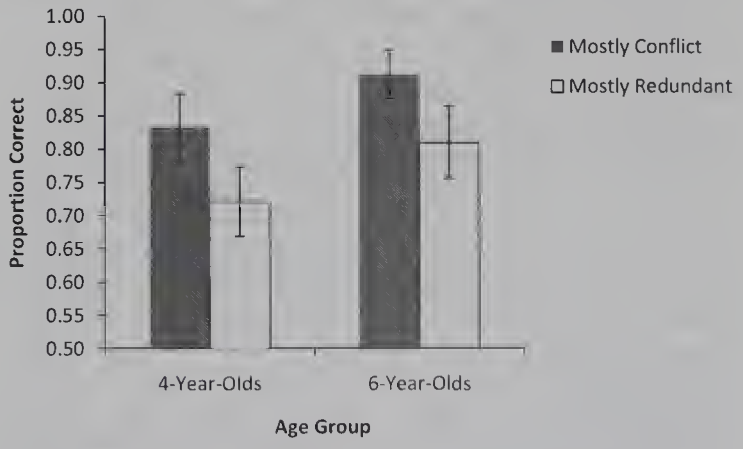

Figure 2. Proportion of conflict cards sorted correctly by age and condition.

Table 1
Means (and Standard Errors) on Working Memory Tasks

	Age group	
Task	4-year-olds	6-year-olds
Visual Counting Span	.59 (.03)	.71 (.03)
Visual Backward Word Span	.63 (.03)	.74 (.02)
Auditory Backward Digit Span	.64 (.04)	.83 (.02)

Working Memory Tasks

For all working memory tasks, each set of items were scored for the proportion of remembered items irrespective of serial order. For example, if the correct response was 2, 3, 6 and the child's response was 2, 6, 4, then that set would be assigned a score of .67 (two correct items out of a possible three items). Then, the average proportion across every set of items was calculated (see Friedman & Miyake, 2005, for advantages using this scoring system).

Means and Correlations Across Tasks

Table 1 displays the means (and standard errors) for all three working memory tasks. As expected, 6-year-olds outperformed 4-year-olds on the Visual Counting Span, $t(63) = 2.7$, $p < .01$, $MSE = 0.028$, $\eta^2 = .10$; the Visual Backward Word Span, $t(63) = 2.9$, $p < .01$, $MSE = 0.023$, $\eta^2 = .11$; and the Auditory Backward Digit Span, $t(63) = 3.5$, $p < .01$, $MSE = 0.048$, $\eta^2 = .16$. Table 2 displays the correlation matrix of all the study variables. To best measure WMC as an individual-differences construct, we created a composite WMC score by standardizing each working memory measure across both age groups and summing them together. Our logic was that because no task is a pure measure of its intended construct, the influence of task-specific variance that is independent of WMC can be minimized, and the influence of WMC-related variance maximized, by averaging across multiple WMC tasks that each make different non-WMC-related demands (see, e.g., Conway et al., 2005; Kane et al., 2004).

WMC as a Predictor of the GN–DCCS

Separate regression analyses were conducted on the proportion of correctly sorted conflict cards in the mostly redundant sort (PROP REDUNDANT), our measure of goal maintenance, and the proportion of correctly sorted conflict cards in the mostly conflict sort (PROP CONFLICT), our measure of response competition. In these analyses, the predictor variables were age (AGE, standardized), the WMC composite (standardized), and the interaction between the two predictor variables (AGE × WMC). Given the multicollinearity between AGE and WMC ($r = .57$, $p < .01$), we opted to enter WMC, the variable of primary importance, into the model as our first step. Then, we entered AGE as our second step and AGE × WMC as our last step.

The regression analysis on PROP REDUNDANT revealed a good overall fit, $F(3, 61) = 2.9$, $p < .05$, $R^2 = .13$, and a significant effect of WMC, $B = .11$, $t(61) = 2.8$, $p < .01$, $\Delta R^2 = .11$. Neither AGE ($\Delta R^2 = .01$) nor AGE × WMC ($\Delta R^2 = .002$) added significantly to the model. Similarly, the regression analysis on PROP CONFLICT revealed a good overall fit, $F(3, 61) = 3.8$, $p < .05$, $R^2 = .16$, and a significant effect of WMC, $B = .10$, $t(61) = 2.1$, $p < .05$, $\Delta R^2 = .15$. Once again, neither AGE ($\Delta R^2 = .005$) nor AGE × WMC ($\Delta R^2 = .004$) added significantly to the model. Thus, our predictions were confirmed that WMC is a significant predictor of performance on both the mostly redundant and mostly conflict card sorts.

Table 2
Correlation Matrix of Study Variables

	Card sorts		Working Memory Span tasks		
	Mostly redundant	Mostly conflict	Visual Counting	Visual Word	Auditory Digit
Age	.28*	.16	.41**	.41**	.55**
Mostly redundant		.39**	.24†	.25*	.31*
Mostly conflict			.38**	.23†	.31*
Visual Counting				.59**	.35**
Visual Word					.47**

†$p < .10$. *$p < .05$. **$p < .01$.

It is also possible that the multicollinearity of the predictors suppressed age differences in our analyses. To determine whether there were differences between age groups, we conducted additional regression analyses for each age group with WMC as the predictor variable. For the mostly redundant card sort, the regression analysis with the 4-year-olds revealed a marginally significant effect of WMC, $B = .03$, $t(35) = 1.7$, $p < .10$, $R^2 = .08$, but a significant effect of WMC with the 6-year-olds, $B = .07$, $t(26) = 2.1$, $p < .05$, $R^2 = .14$, confirming that WMC predicts performance across both ages. In contrast and as expected, the regression analysis for the mostly conflict card sort revealed a significant effect of WMC for the 4-year-olds, $B = .05$, $t(35) = 2.8$, $p < .01$, $R^2 = .18$, but not the 6-year-olds, $B = .01$, $t < 1$, $R^2 = .01$.

Finally, we sought to determine whether WMC predicted variance for each sort above and beyond the other sort. To accomplish this, we included PROP CONFLICT in the first step of the regression on the mostly redundant sort, and likewise included PROP REDUNDANT in the first step of the regression on the mostly conflict sort. For these analyses we once again entered AGE as a predictor (i.e., we analyzed the entire sample together).

The regression analysis for the mostly redundant card sort revealed that PROP CONFLICT was a significant predictor of performance, $\Delta R^2 = .15$, $p < .01$, and that WMC accounted for a marginally significant amount of additional variability, $\Delta R^2 = .04$, $p < .10$. Similarly, the regression analysis for the mostly conflict card sort revealed that PROP REDUNDANT was a significant predictor of performance, $\Delta R^2 = .15$, $p < .01$, and that WMC accounted for a significant amount of additional variability, $\Delta R^2 = .07$, $p < .05$. In neither case did AGE nor AGE × WMC contribute significantly to the model.

Discussion

WMC has been associated with a wide range of cognitive skills that involve shifts of attention and executive control (Engle & Kane, 2004; Gathercole et al., 2008). The current study was designed to assess whether WMC was predictive of the ability to maintain a novel goal in young children. The results demonstrated that both 4- and 6-year-old children with higher WMC were more successful in goal maintenance, as measured by performance on the mostly redundant sort. This finding is consistent with Kane and Engle's (2003) report that WMC was related to goal maintenance in adults and extends previous research by demonstrating the relation between working memory and goal maintenance in young children. The current findings refute the idea that young children in general simply do not have the capacity to maintain a representation over a period of inactivity, and thus emphasize the importance of individual differences in WMC on the execution of goal-directed behavior.

WMC also predicted performance on the mostly conflict sort for 4-year-olds but not for 6-year-olds. We interpret 4-year-olds' higher performance on the mostly conflict sort compared with the mostly redundant sort as evidence that they benefit from the constant execution of the rule. However, because they still have some difficulty maintaining the rule, there are individual differences based on WMC. In contrast, 6-year-olds generally possess a higher WMC (relative to 4-year-olds) that is sufficient to take full advantage of the scaffolding afforded by the mostly conflict task, and so WMC-related individual differences were absent. In addition, the success of 6-year-olds (relative to 4-year-olds) on the mostly conflict sort must be independent of WMC and suggests that other age-related processes might be contributing to success. One candidate is the ability to switch flexibly from one response set to another (i.e., set shifting; Cragg & Chevalier, in press; Garon, Bryson, & Smith, 2008; Miyake et al., 2000), a process that is not tested directly in our measure of WMC but is clearly needed to succeed on the mostly conflict sort. Indeed, vast improvements in set shifting have been reported in young children, especially between 3 and 6 years of age (e.g., Chevalier & Blaye, 2008; Deak, 2000; Zelazo et al., 2003).

We argue that the two card sorts are tapping into related but separable abilities. This is because: (a) WMC predicts common variance for both card sorts along with unique variance for each card sort, (b) the modest correlation between performance on these two sorts ($r = 0.39$, $p < .01$) suggests that these factors are interrelated but separable, and (c) there are different patterns of performance for 4- and 6-year-olds on the card sorting tasks. As argued earlier, this is consistent with Engle and Kane's (2004) two-factor theory of working memory and extends the theory to early childhood. Importantly, we now have some empirical evidence that each factor can be measured by its own card sort. Clearly, additional research needs to be conducted that speaks to the extent that each card sort assesses each factor, and the importance of assessing the development of each factor independently.

The findings from the current study have direct implications for implementing ways to improve goal-directed behavior. From our perspective, goal maintenance can be enhanced in children who undergo specific training in working memory. This idea is supported by recent research from Diamond, Barnett, Thomas, and Munro (2007) who have used the Tools curriculum to train low income preschool children on a variety of executive function tasks in an effort to improve executive control, the central component of working memory as conceptualized by Engle and Kane (2004; see also Baddeley, 2007). Vast improvements were seen on several measures, including the Dots task, which interleaves congruent and incongruent trials in a similar manner to the GN–DCCS.

In sum, individual differences in working memory predict goal neglect even in young children. These results highlight the utility of this paradigm to set the groundwork for future studies designed to investigate the specific mechanisms involved in the development of working memory.

The Social Costs of Academic Success Across Ethnic Groups

Thomas E. Fuller-Rowell
University of Michigan

Stacey N. Doan
Boston University

This study explores the longitudinal association between academic achievement and social acceptance across ethnic groups in a nationally representative sample of adolescents (N = 13,570; M_{age} = 15.5 years). The effects of school context are also considered. Results show that African American and Native American adolescents experience greater social costs with academic success than Whites. Pertaining to school context, findings suggest that the differential social consequences of achievement experienced by African Americans are greatest in more highly achieving schools, but only when these schools have a smaller percentage of Black students. Students from Mexican descent also showed differential social costs with achievement in particular contexts. The implications of these findings to theory, policy, and future research are discussed.

Despite significant progress being made toward closing ethnic gaps in achievement, their relative stability over the past two decades has raised their priority within the broader political agenda and caused them to become recognized as one of the most important civil rights issues of the 21st century (Paige, 2004). Across virtually all measures, Black, Hispanic, and Native American students in the United States earn lower grades, drop out more often, and attain less education than Whites or Asian Americans (Perie & Moran, 2005). While structural and social burdens, often experienced disproportionately by minorities, such as socioeconomic status (McLoyd, 1990), single-parent families (Pong, 1998), and school or neighborhood disadvantage (Brooks-Gunn, Duncan, Klebanov, & Sealand, 1993) are important factors to consider, the dynamics of social acceptance among academically stigmatized groups are also of theoretical and practical interest (Ogbu, 2004; Spencer, Cross, Harpalani, & Goss, 2003; Steele, 1998).

Social acceptance, particularly critical during adolescence when the opinions and judgments of peers become increasingly important, is considered a basic need, closely tied to motivation and behaviors (Baumeister & Leary, 1995). Research exploring the association between achievement and social acceptance suggests a positive cyclical relation, achievement leading to greater social acceptance and social acceptance leading to greater levels of achievement (Chen, Rubin, & Li, 1997; Wentzel, 1991, 2005). These findings, combined with evidence that social acceptance is an essential component of adolescent self-worth (Harter, 1999), suggest that any breakdown in this relation could have particularly adverse consequences to development. The extent to which particular ethnic groups experience differential social costs with achievement is therefore an important area of research and theory.

Theories Predicting Differences Across Ethnic Groups in the Social Costs of Achievement

To understand the current experiences and perspectives of a particular minority group, it is important to consider the history of the group's relationship to the dominant culture (Fordham & Ogbu, 1986; Ogbu, 1999, 2004). Specifically, in their oft-cited paper, Fordham and Ogbu (1986) argue that involuntary minority groups, such as African Americans and Native Americans, whose presence

in the United States stems back to colonization and enslavement, have developed a collective identity in opposition to the mainstream White culture. Furthermore, Ogbu and colleagues suggest that, for these groups, academic success may be stigmatized by peers as ''acting White,'' and thus attainment of higher grades in school may have differential social consequences (Ogbu & Simons, 1998).

Several scholars, however, have challenged the conceptual underpinnings of this perspective. Cross (2003), for example, has argued that resistance to education is in no way fundamental to African American culture and that the roots of achievement problems lie not in the legacy of slavery but within specific structural inequalities that have and still continue to directly affect minority groups. Furthermore, Spencer and Harpalani (2008) argue that Ogbu and colleagues make broad unwarranted assumptions that decontextualize and overgeneralize the experiences of African American youth while ignoring the importance of meaning-making processes. In particular, Spencer and Harpalani emphasize that the ''acting White'' phenomenon is not a cultural syndrome that is pervasive, but rather a coping mechanism: a reaction to stereotypes and experiences of discrimination experienced in particular contexts.

Spencer and colleagues therefore articulate an alternative interpretation of the ''acting White'' phenomenon that focuses on processes of identity development, and experiences with stigma and discrimination (e.g., Spencer & Harpalani, 2008; Spencer, Noll, Stoltzfus, & Harpalani, 2001; Spencer et al., 2003). Important to this perspective are normative developmental processes during adolescence. Specifically, adolescence is an important time for youth to engage in identity exploration in various domains (e.g., career, ethnic identity). Although members of the majority group generally take their ethnic identity for granted, ethnic minority adolescents have the additional task of having to negotiate the meaning of their membership in a group whose customs may often be devalued by mainstream society (Cross, 1991; Phinney, 1990; Spencer & Markstrom-Adams, 1990). As part of this identity formation process, Cross (1991) has described that ethnic minorities often go through a stage referred to as immersion-emersion, in which they immerse themselves within their own ethnic culture and have a tendency to reject the perspectives of the dominant group.

During this sensitive stage of identity development, minority adolescents tend to react to negative academic stereotypes directed toward their group in a particular context by labeling behaviors associated with success within that context as ''acting White'' (Spencer et al., 2003). Spencer and colleagues, therefore suggest that the ''acting White'' phenomenon is not the result of a broad cultural frame of reference (as Ogbu's theory suggests) but rather the result of a particular coping response to negative stereotypes that are experienced in specific contexts. From this perspective, it is the current stigmatization of minority groups that drives some adolescents to reject expectations and values of the dominant group, rather than any inherent oppositional orientation toward schooling. Under Spencer's framework, stigmatized minority groups other than African Americans would therefore also be expected to experience social costs with academic success. Furthermore, contextual factors, such as school characteristics, would also be expected to play an important role.

The theory of stereotype threat is also of direct relevance to the proposition that academic achievement may be coming at a greater social cost for particular groups. Steele (1997, 1998) has discussed how the burden of academic stereotypes, and the prolonged exposure to such stereotypes at the group level, may create social costs with achievement for members of stigmatized groups. According to this perspective, when individuals become aware of a negative stereotype directed toward their group, they experience anxiety related to the possibility of conforming to the stereotype, which in turn affects their performance. Thus, as a self-protective mechanism, prolonged exposure to negative stereotypes in a particular domain is thought to be associated with psychological disengagement from that domain (Davies, Spencer, & Steele, 2005; Osborne, 1997; Steele, 1997). Steele's work, therefore, suggests that the collective devaluing of academics among stereotyped groups may lead individuals who are part of those groups to experience greater social costs with achievement (Steele, 1997).

Related Empirical Findings

Support for the ''acting White'' proposition has been derived from several ethnographic studies of African American students, conducted across multiple contexts (e.g., Fordham & Ogbu, 1986; Ogbu, 1999). These studies generally found that attitudes and behaviors conducive to academic attainment, such as studying, reading, and participating in class, are often stigmatized as ''selling out'' or ''acting White'' (e.g., Fordham & Ogbu, 1986).

Other more recent qualitative studies, however, have failed to find that Black adolescents experience any oppositional orientation toward achievement (e.g., Akom, 2003; Tyson, 2002).

Additionally, the few quantitative studies that have examined the social costs of academic success have thus far failed to establish that achievement leads to greater social costs for particular groups. Specifically, using data from the National Educational Longitudinal Study (NELS), two studies have attempted to test the proposition that African Americans experience greater social costs with academic success (Ainsworth-Darnell & Downey, 1998; Cook & Ludwig, 1997). The NELS survey included self-report measures of academic achievement, popularity, and harassment. Using these measures, both studies found no evidence to suggest that African American students experienced greater social costs with achievement.

While this research calls into question the social costs proposition, findings from these studies are limited in several ways. First, both studies are based on the same dataset and therefore do not offer an independent replication of findings. Second, neither study uses a longitudinal design to test the association between achievement and social acceptance: Both studies only considered associations between self-report items within a single time point. Furthermore, these studies only look at a narrow age range and do not compare social costs across all of the major U.S. pan-ethnic groups. Finally, neither study uses multilevel modeling techniques, which allow for a more adequate consideration of individual and school-level variables (Raudenbush & Bryk, 2002).

The Importance of School Context

Individuals develop within particular environmental contexts, and these contexts play a pivotal role in development (Bronfenbrenner, 1979; Spencer, 1999). The environment of a school, specifically its achievement level and the proportion of same-race students in the school, may play an important role in moderating the relation between achievement and social acceptance. Research examining intergroup relations, for example, has demonstrated that in competitive or high-achieving contexts, where both groups are being evaluated on the same criterion, racial tensions and discrimination are likely to increase (see Brewer & Kramer, 1985 for a review). Furthermore, recent qualitative data suggest that competitive schools may breed an environment of animosity, particularly when there is a disproportionate underrepresentation of disadvantaged students (Tyson, Darity, & Castellino, 2005).

The proportion of same-race students in a school is therefore also an important factor that may influence the social costs of academic success for minority adolescents. Specifically, with more same-race students present, it is possible that experiences of stigmatization and discrimination may occur less often or be less pronounced. Along these lines, researchers have argued that in largely Black schools, students are less likely to associate racial characteristics with achievement and therefore less likely to stigmatize achievement-related behaviors (O'Connor, Fernandez, & Girard, 2007). Furthermore, students in largely Black schools have been found to hold more proschool attitudes (Goldsmith, 2004), and higher levels of school attachment (Johnson, Crosnoe, & Elder, 2001). This work suggests that the social costs of academic success may be ameliorated for minority students in schools with a higher proportion of same-race students.

Purposes of the Current Study

The purpose of this article is to explore the association between achievement and social acceptance across ethnic groups in a nationally representative sample of adolescents. Specifically, we will consider the social costs of achievement for all of the major pan-ethnic groups in the United States (non-Hispanic Whites, African Americans, Hispanics, Asians, and Native Americans), as well as subgroups within the Hispanic and Asian pan-ethnic categories. We will then determine whether socioeconomic and contextual factors (family socioeconomic status [SES], school SES, family structure, school-level achievement, school safety, school type, and school size) are able to account for any differences in social costs across groups. Based on the theories discussed (Ogbu & Simons, 1998; Spencer & Harpalani, 2008; Steele, 1998), we hypothesize that even after accounting for background factors, stigmatized ethnic groups, such as African Americans, Hispanic Americans, and Native Americans, will, on average, experience greater social costs with achievement than Whites.

Having established differences across groups, we will then explore factors that may account for variation in social costs within groups. Specifically, gender and immigrant status will be considered as potential moderators of social costs. With respect to gender, previous work suggests that the dynamics of stigma and achievement are somewhat more problematic for African American men than women (e.g., Graham, Taylor, & Hudley, 1998; Osborne, 1997). Thus, gender will be explored as a potential moderator.

Additionally, a number of scholars have argued that immigrant status is an important factor explaining differences in attitudes toward academic attainment (e.g., Portes & Zhou, 1993; Spencer et al., 2003). Furthermore, research has indicated that immigrant status influences the extent to which discrimination is perceived (Finch, Kolody, & Vega, 2000). Based on this work, we will test the hypothesis that more recent Hispanic, Asian, or Black immigrants experience lower social costs with academic success than their more recent immigrant counterparts.

Our final analyses will focus on exploring whether social costs are dependent on school context. Specifically, based on the research discussed before, we will consider whether the racial composition and achievement level of a school moderate the relation between academic achievement and social acceptance. In relation to school context, we hypothesize that minority groups will show higher social costs with academic success in higher achieving schools. We also hypothesize that the presence of same-race students will serve as a protective factor in these contexts, buffering the level of social costs experienced with academic achievement.

Method

Data

The current study utilizes data from the National Longitudinal Study of Adolescent Health (Add Health). Add Health is an ongoing nationally representative study of 7th through 12th graders selected from 80 high schools and 52 feeder (middle and junior high) schools in 1994. All available students in each of the participating schools initially completed the In-School Questionnaire ($n = 90{,}118$). A subsample of students then completed the Wave I In-Home Interview ($n = 20{,}745$) in 1995, followed by the Wave II In-Home Interview in 1996 ($n = 14{,}738$). In-Home Interviews can also be linked to school-level data reported by school administrators, as well as to data from parent interviews.

Sample

The sample for the current study consisted of adolescents who participated in both the Wave I and Wave II In-Home Interviews, and were assigned a valid sample weight as part of the Add Health nationally representative sample ($n = 13{,}570$; see Chantala & Tabor, 1999, for details on the Add Health sampling procedures). Sample descriptive statistics by pan-ethnic group are presented in Table 1, and are described in the Results section.

Models containing only individual-level variables (Models 1–3, 5, and 6) excluded 5% of cases owing to missing values on one or more covariates. Additional models (Model 4, and Models 7 through 15), also excluded schools with missing school-level data and therefore had slightly higher levels of overall missingness (approximately 7% of cases). Those who were excluded from analyses as a result of missing data were not found to be different from those included in the analysis on any of the background or substantive variables considered in the

study (all point-biserial and phi correlations were below a magnitude of .10). The exclusion of cases with missing data was therefore assumed to add little substantive bias to the reported results.

Measures

Race and ethnicity. Racial and ethnic categories were created based on self-report items from the Wave I In-Home Interview. Participants first reported whether they are of Hispanic origin. Next, participants indicated the racial category or categories they belong to (Asian, Black or African American, Native American, White, or Other). Those who reported being part of two or more categories were classified as mixed racial, and the remaining individuals were classified into the standard categories of non-Hispanic Black, non-Hispanic White, non-Hispanic Asian, non-Hispanic Native American, and Other. Sample sizes and demographics for each racial category are included in Table 1. In addition to the pan-ethnic groups described before, individuals who identified themselves as Hispanic or Asian also identified the specific subgroup(s) that they belong to. For Hispanics, we consider Mexican ($n = 1041$), Puerto Rican ($n = 336$), Cuban ($n = 294$), and Central or South American ($n = 195$) groups separately for some analyses. For Asians, we consider Chinese ($n = 191$) and Filipino ($n = 360$) groups separately. Other Asian subgroups were not considered because of small sample sizes.

Grade point average. Grade averages at Wave I were calculated from self-reports of achievement in each of the four major subject areas (English or language arts, history or social studies, mathematics, and science). Participants were asked to report their grade at the most recent grading period on a 4-point scale from *A* to *D or lower*. The four items were averaged to create an overall score ranging from 1 (*all Ds or lower*) to 4 (*all As*) representing each participant's grade point average (GPA) at Wave I (Cronbach's $\alpha = .75$). The four item scale was then standardized for use in the reported models. Self-reported GPA has been shown to be highly correlated with actual GPA and therefore can be considered an adequate proxy for actual levels of achievement (Gonzales, Cauce, Friedman, & Mason, 1996).

Social acceptance. Social acceptance was measured using four items from the Wave I and Wave II In-Home Interviews. Scale items map closely onto established conceptualizations of perceived social support, loneliness, and sense of belonging (e.g., Hagerty & Patusky, 1995; Russell, 1996). The term *social acceptance* is therefore used broadly in this article to encompass all three of these closely related concepts. The first item asked participants how strongly they agree or disagree that they "feel socially accepted." Responses for this item were on a 5-point scale ranging from *strongly agree* to *strongly disagree.* The remaining three items asked participants to report how often in the past week "people were unfriendly" to them, how often they "felt that people disliked" them, and how often they "felt lonely." Responses to these items were on a 4-point scale ranging from *never or rarely* to *most of the time or all of the time.* Items were standardized, and averaged such that higher scores indicated higher levels of social acceptance (lower levels of social isolation). A log transformation was performed to reduce skewness and robust standard errors were used in all reported models to account for remaining deviations from normality. The average interitem correlation for the scale was .32, and the internal reliability was .65 at Wave I and .66 at Wave II. These are equivalent to reliabilities of .79 and .81 for an eight-item scale with equivalent interitem correlations (Cronbach, 1951). Internal reliability of the scale was also very similar across ethnic groups (.66 for Whites, .64 for African Americans, .65 for Hispanics, .63 for Asians, and .63 for Native Americans). Furthermore, exploratory and confirmatory factor analyses both suggested that a single factor structure was the most appropriate solution for all five pan-ethnic groups.

Individual-level disadvantage. SES and family structure were considered as indicators of individual-level disadvantage. SES was measured from youth reports of the highest level of education obtained by a currently residing parent. Level of education was recoded to the following 4-point scale: 1 = *less than high school,* 2 = *graduated from high school or obtained a GED,* 3 = *some college or post-high school technical training,* and 4 = *graduated from college or more.* Where youth reports were missing, parent self-reports were used to minimize missing data (parents responded to an identical question with the same response categories). Family structure was dummy coded with 1 indicating single parent family.

Other individual-level variables. Age, gender, and immigrant status were also included in multilevel models. Immigrant status and age were based on youth reports. Immigrant status was dichotomously coded with 1 indicating a foreign-born mother or primary caregiver. Coding immigrant status in this manner is synonymous with comparing first- and second-generation adolescents (foreign-born parents [FBPs]) with third-generation or greater adolescents (U.S.-born parents). Age was mean centered so that the model intercepts remained interpretable as the average aged adolescent. Gender was recorded by the Add Health interviewer during the Wave I In-Home Interview and was dichotomously coded with 1 indicating men. Population means and standard deviations for all individual-level variables are reported in Table 2.

School-level variables. At the school level, five measures of school disadvantage were considered: safety, SES, achievement, size, and type (public vs. private or Catholic). Means and standard deviations for all school-level variables are reported in Table 3. With respect to safety, all students who completed the In-School Survey (a near census of each school) were asked how strongly they agree or disagree that they "feel safe at school." By aggregating responses to this item, average levels of safety were calculated for each school. An identical procedure was also carried out to compute an aggregated school-level SES score based on student reports of parent education from the In-School Survey. This aggregation method is akin to techniques used in previous Add Health studies (e.g., Crosnoe, Cavanagh, & Elder, 2003).

School-level achievement was measured using indicators of grades and test scores. Although both grades and test scores have unique limitations as

measures of school-level achievement (Hanushek & Taylor, 1990; Willingham, Pollack, & Lewis, 2002), the two measures together are better able to capture achievement at the school level (Clark & Watson, 1995). School-level grades were calculated by aggregating student reports of their GPA from the In-School Survey. School test scores, on the other hand, were taken from school administrator reports of the percentage of students testing above and below grade level. The percentage of students testing below grade level was subtracted from the percentage of students testing above grade level, yielding a measure of the extent to which there was a preponderance of students in a given school with high test scores. These two indicators of school-level achievement were then standardized and averaged ($r = .46$, $p < .001$). School size and school type were based on school administrator reports of the size of the school (total student enrollment) and whether the school was public, private, or Catholic. The school size variable was log-transformed to reduce right skewness, and a dichotomous variable was created for school type such that 1 indicated a school that was not public (i.e., private or Catholic).

With respect to the percentage of Black students, a dichotomous school-level variable was created indicating a school in the top quartile with respect to the percentage of Black students. Of the 132 schools surveyed as part of the Add Health nationally representative sample, 33 fell into this category. These schools had student bodies with an average of 47% Black students ($SD = 20.7$). This variable therefore indicates schools where Black students are either the majority ethnic group in the school, or a substantial portion of the overall student body. The use of a dichotomous variable in this context is in line with the perspective that a critical mass of a particular group is necessary to change intergroup dynamics (Etzkowitz, Kernelgor, Neuschatz, Uzzi, & Alonzo, 1994). A second dummy variable was also created to indicate schools in the top quartile with respect to the percentage of Hispanic students. Twenty-four schools fell into this category. These schools had an average of 42% Hispanic students ($SD = 20.6$). While continuous variables relating to the percentage of Black and Hispanic students in a school were also explored, we found that dichotomous variables were better able to capture differences between schools in social costs for particular groups. The indicator variables are therefore used in the analyses presented in this article. All continuous variables were z-scored in the models presented.

Analysis Plan

Analyses for the current study involved multilevel modeling of individual- and school-level variables (Raudenbush & Bryk, 2002). Because Add Health data collection was school-based, we included a random effect for school in each of our models as well as a random slope component for the relation between grades and social acceptance. Including random effects allowed us to account for within-school clustering of the data and therefore to accurately assess the significance of model parameters. Multilevel models also allowed us to consider individual-level variables, school-level variables, and cross-level interactions simultaneously.

Four multilevel models were estimated to address questions relating to ethnic group differences in the relation between achievement and social acceptance: Model 1 focused on establishing the overall effect of GPA at Wave I on subsequent changes in social acceptance, Model 2 tested whether this relation differed across ethnic groups, and Models 3 and 4 determined whether differences across groups could be explained by other individual- and school-level factors. After establishing the relation between grades and social acceptance for each ethnic group, the next model focused on testing whether immigrant status may be affecting social costs for particular ethnic groups. Specifically, Model 5 considered whether Hispanic, Asian, or Black youth from immigrant families show lower social costs with achievement than those from families with U.S.-born parents. Model 6 then considered whether African American men experienced more social costs than women.

The last set of models focused on exploring potential school-level contingencies of the relation between grades and social acceptance: Model 7 looked at whether social costs for Black students were greater in schools with higher levels of achievement, Model 8 looked at whether Black students in largely Black schools experienced lower social costs than those in less Black schools, and, finally, Model 9 considered whether the effects of school achievement on social costs depended on the proportion of Black students in the school.

Similar models also tested the social consequences of achievement for Hispanic students as a function of school-level achievement and the percentage of Hispanic students in the school (Models 10, 11, and 12). The effects of school context were also considered for individual Hispanic ethnic groups (Mexican, Puerto Rican, Cuban, and Central or South American) and Asian ethnic groups

(Chinese, and Filipino). Models 13, 14, and 15, for example, tested the effects of school contexts for adolescents from Mexican descent, and subsequent models tested context effects for the other Hispanic and Asian ethnic groups. Context effects could not be considered for Native Americans because of sample size limitations.

Because the Add Health sampling frame was stratified by various school characteristics, and because various subgroups of individuals were oversampled, it was important to account for sample weights in all of our analyses. In addition to adjusting for the probability of selection at the level of both school and individual, sample weights also adjust for survey nonresponse between the Wave I and Wave II In-Home Interviews (Chantala & Tabor, 1999). This corrects for potential bias to the sample that may have been added with attrition between the first and second waves. All of the models presented in the current study are estimated using the gllamm procedure within Stata (Rabe-Hesketh, Pickles, & Skrondal, 2001; StataCorp, 2007).

Results

Descriptive Analysis and Correlations

All analyses presented in this article account for the Add Health sampling strategy and are therefore representative of the adolescent population in the United States at the time the data were collected. Means differences were first considered across the different ethnic groups. Overall, ethnicity accounted for a significant portion of the variance in each of the variables considered. Ethnic group differences among individual-level variables are presented in Table 1.

Correlations between individual-level variables are presented in Table 2 along with estimated population means and standard deviations for each variable. All correlations above .02 are significant at the 95% confidence level. As expected, social acceptance was found to be positively correlated with GPA ($r = .13$, $p < .001$). Associations between school-level variables are presented in Table 3 along with estimated population means and standard deviations.

Multilevel Models

Longitudinal association between GPA and social acceptance. A series of models were estimated to address our hypotheses. Random effects for the intercept and slope were included in all models. Models 1 through 4 are presented in Table 4. Model 1 estimated the relation between grades and social support controlling for individual-level covariates. Based on previous research (Chen et al., 1997; Wentzel, 1991, 2005), we expected that, on average, there would be a positive association between GPA and social acceptance. In line with our prediction, GPA at Wave I did significantly predict positive changes in social acceptance.

Several demographic variables were also found to be predictive of changes in social acceptance: Men, higher SES adolescents, and younger adolescents all tended to have more positive changes in social acceptance over time. Additionally, Asians had less positive changes than Whites. The variance component associated with the random slope coefficient in Model 1 was also found to be significant ($p < .001$). This suggests that the relation between Wave I GPA and Wave II social acceptance does vary across schools, and provides justification for later models to look at school-level characteristics as moderators of this relation.

Ethnic group differences in the relation between GPA and social acceptance. Having established the direct association between GPA and social acceptance, Model 2 added the GPA by race interaction terms to test for ethnic group differences in social costs with academic success. Parameter estimates for Model 2 indicated that African American adolescents have a significantly weaker (more negative) relation between GPA and social acceptance than Whites. Specifically, while Whites (the reference group in Model 2) show a relatively strong positive association, the association for African Americans is negative, suggesting that there are differential social consequences with achievement for African Americans. While less Native Americans were present in the sample, as compared with Whites, they also showed significant social costs with achievement. Based on estimates from Model 2, Figure 1 shows the effect of Wave I GPA on subsequent changes in social acceptance for Whites, African Americans, and Native Americans. Although the relation between achievement and social acceptance was most negative for Native Americans, the difference between African Americans and Native Americans was not significant. Interaction terms for Hispanics and Asians in Model 2 were not significant, suggesting that the relation between grades and social acceptance for these groups tend, on average, to be the same as for Whites. In separate analyses, Hispanic and Asian subgroups were also

considered, but no differential social consequences were found.

Does disadvantage account for ethnic group differences in social costs? As African American and Native American adolescents are more likely than Whites to be from low-SES families, single-parent families, and disadvantaged schools, our next goal was to determine whether the significant interaction effect for African Americans and Native Americans might be accounted for by controlling for individual- and school-level disadvantage. Model 3 therefore added individual-level interactions

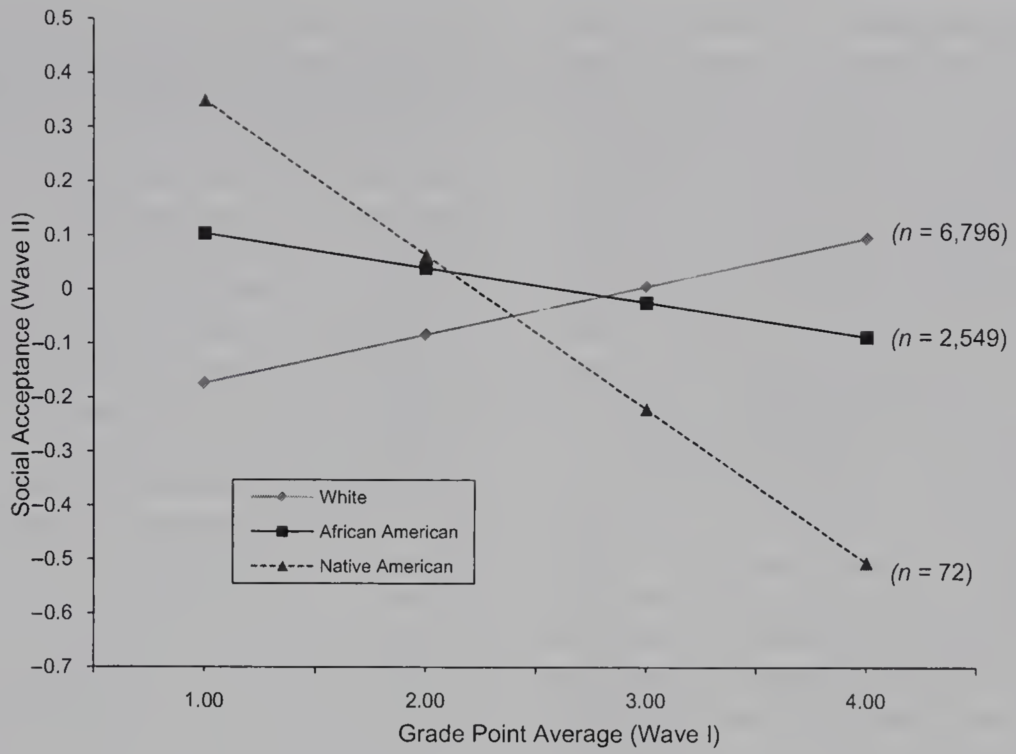

Figure 1. Fitted interaction plot depicting the relation between Wave I grade point average (GPA) and Wave II social acceptance for Black, Native American, and White adolescents.
Note. This figure is based on parameter estimates from Model 2 (Table 4), with GPA converted back to its original 4-point scale.

(GPA × SES; GPA × Single Parent) as competing moderators and found that although the GPA × Black and GPA × Native terms decreased slightly (by 6% and 2%, respectively), both effects remained significant. Model 4 then controlled for the effects of school disadvantage on the relation between grades and social acceptance. However, the GPA × Black interaction term remained highly significant, as did the GPA × Native term. Findings from these models suggest that individual- and school-level factors do not account for the differential social costs with academic success found for African Americans and Native Americans.

Is immigrant status a key variable influencing social costs? The next model considered whether less recent Hispanic, Asian, or Black immigrants show more social costs with academic success than their more recent immigrant counterparts. To test these effects, Model 5 included three-way interactions between GPA, race, and immigrant status. Parameter estimates for this model suggested that immigrant status did not play an important role for any of these groups. Specifically, with respect to the relation between grades and social acceptance, Hispanic adolescents with FBPs are not significantly different from Hispanic adolescents with U.S.-born parents (GPA × Hisp. × FBP: $B = -.080$, $SE = .115$, *ns*). Asian and Black adolescents also showed no differences in social costs with respect to immigrant status (GPA × Asian × FBP: $B = -.031$, $SE = .148$, *ns*; GPA × Black × FBP: $B = -.167$, $SE = .157$, *ns*). Unrelated to hypotheses for the current study, we also inadvertently discovered, in Model 5, that the main effect for Asians reported in Model 1, suggesting greater decreases in social acceptance, is being entirely driven by the effect for Asians with FBPs (Asian × FBP: $B = -.338$, $SE = .148$, $p < .05$). This suggests that Asian adolescents growing up in families with FBPs (first and second generations) tend to experience greater decreases in social acceptance across the adolescent period than Whites, while Asian adolescents from families with U.S.-born parents (third generation or greater) do not show greater decreases.

Does the social costs effect depend on gender? Model 6 tested for differences in social costs for African American men and women. Parameter estimates for this model suggest that no significant differences were present between men and women (GPA × Male × Black: $B = .040$, $SE = .065$, *ns*). Gender differences were also explored for each of the other ethnic groups and none were found to be significant. Models 5 and 6 (relating to immigrant status and gender) were not included as a table as a result of nonsignificant findings. A table detailing the parameter estimates for these models is available from the first author upon request.

School-level moderators of social costs for African Americans. The next set of models focused on exploring contingencies of the relation between grades and social acceptance for African Americans. (Because of the small sample size for Native Americans, it was not possible to consider differences across schools for this group.) Models 7 through 9 are presented in Table 5. Model 7 focused on the interaction between GPA, Black race, and school-level achievement to determine whether being in a higher achieving school is associated with more social costs for African Americans. Results for this model suggested that when considered alone, school-level achievement did not significantly affect the social costs of academic success for African Americans. Model 8 focused on the interaction between GPA, Black race, and Black school to determine whether being in a largely Black school might be protective against the social costs of academic success for African Americans. Results for this model also proved nonsignificant suggesting that, overall, the social costs of academic success for African Americans are not significantly different in largely Black schools.

Model 9 focused on testing whether the effects of being in a high-achieving school might depend on the proportion of Black students in the school or, in other words, whether it is important to consider school-level achievement and school racial context simultaneously. Parameter estimates from this model showed a significant interaction effect such that Black students in more high-achieving schools had greater social costs, but only when the school had a smaller percentage of Black students. This model therefore suggests that a more Black school context is protective against social costs when the school is high achieving.

With respect to model parameters, because the Black school variable (BlkSch) is dummy code, the significant GPA × Blk × SchAch term in Model 9 suggests that African American students in higher achieving non-Black schools have greater social costs with academic success than Black students in lower achieving non-Black schools ($B = -.232$, $SE = .098$, $p < .05$). The GPA × Blk × BlkSch × SchAch term shows that the increase in social costs as a result of being in a high-achieving school is almost completely eliminated if the school is largely Black ($B = .222$, $SE = .015$, $p < .05$). In other words, African Americans in higher achieving (+1 *SD* on school-level achievement), less Black schools are experiencing the greatest social costs with academic success, whereas African Americans in high-achieving Black schools are experiencing lower social costs. Figure 2 illustrates the school-level findings for four groups of Black students: Black students in *high-achieving non-Black schools*; Black students in *high-achieving Black schools*; Black students in *low-achieving non-Black schools*; and Black students in *low-achieving Black schools*. The slopes of the lines for Black students in low-achieving Black and non-Black schools are not significantly different from each other or from the slope of the line for Blacks in high-achieving Black schools. On the other hand, the slope of the line for Black students in high-achieving non-Black schools is significantly different from the others, indicating that Black students in these schools, on average, experience the greatest social costs with achievement.

School-level moderators of social costs for Hispanics. Additional models focused on the effects of context for Hispanics as well as for specific Hispanic ethnic groups. Specifically, our first set of models looked at the social consequences of achievement for Hispanic students as a function of school-level achievement and the percentage of Hispanic students in the school. Results of these analyses (Models 10, 11, and 12) suggested that school-level achievement and the proportion of Hispanic students in a school do not play a role for Hispanics.

We then considered whether school characteristics may have differential consequences for the Hispanic subgroups: Mexican, Puerto Rican, Cuban, and Central or South American. These analyses revealed that the school-context findings reported for Black students were replicated for Mexican students (Models 13, 14, and 15). Tables of the full models are not included owing to space limitations but are available from the first author upon request. Models 13 and 14 showed that school-level achievement and the percentage of Hispanic students in the school, when considered separately, did not significantly moderate the relation between achievement and social acceptance. However, when considered together, in Model 15, the same findings emerged as for African American students. Specifically, model parameters showed that Mexican students experience greater social costs with achievement in high-achieving schools ($B = -.236$, $SE = .107$, $p < .05$), but only when these schools do not have a substantial portion of Hispanic students ($B = .277$, $SE = .109$, $p < .05$). In other words, just as Black students experienced lower social costs with achievement in higher achieving Black schools, Mexican students also experienced lower social costs in higher achieving Hispanic schools. Figure 3 illustrates the school-level findings for students from Mexican descent. Specifically, Mexican students in higher achieving (+1 *SD* on school-level achievement) less Hispanic schools are shown to be experiencing the greatest social costs with

achievement, whereas Mexican adolescents in other school contexts enjoy a positive association between achievement and social acceptance (as evidenced by the positive slopes for the other three lines). The slopes of the lines for Mexican students in low-achieving Hispanic and non-Hispanic schools are not significantly different from each other or from the slope of the line for Mexican students in high-achieving Hispanic schools. On the other hand, as indicated before, the slope of the line for Mexican

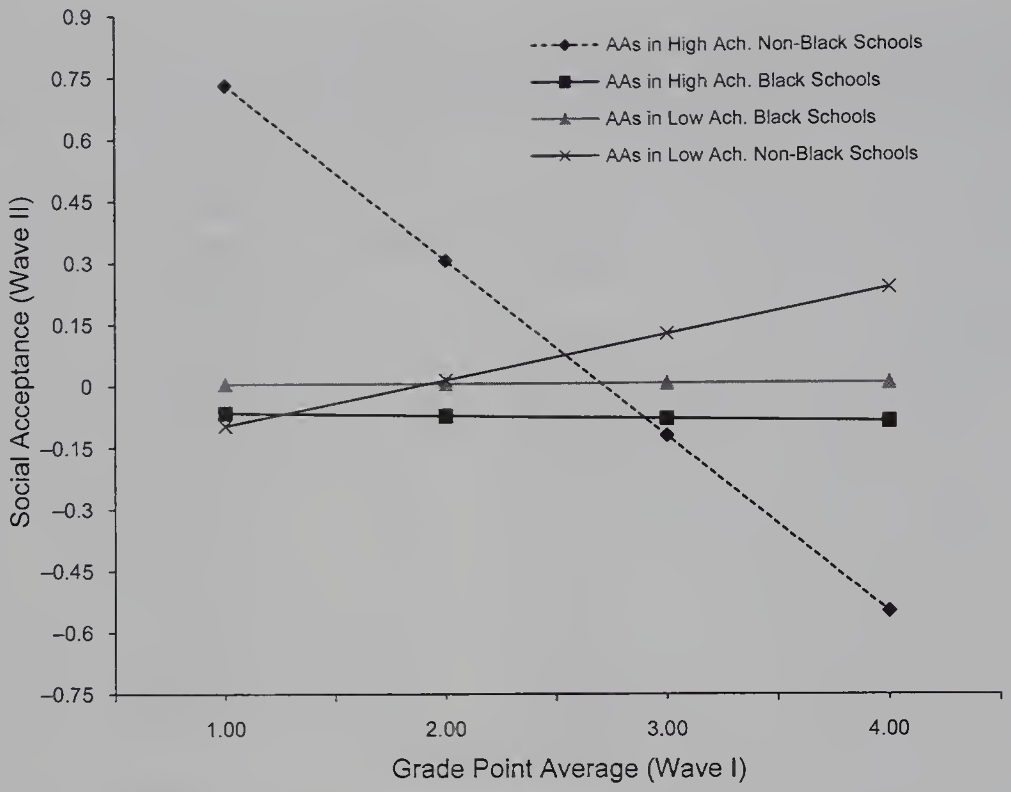

Figure 2. Fitted interaction plot depicting the relation between Wave I grade point average (GPA) and Wave II social acceptance for Black adolescents in four school contexts.
Note. This figure is based on parameter estimates from Model 9 (Table 5), with GPA converted back to its original 4-point scale. Sixty-eight percent of Black students (n = 1,708) are in Black schools (top quartile of percent Black), and 32% (n = 801) are in less Black schools. As school-level achievement is a continuous variable, specific sample sizes cannot be associated with each of the lines: high-achieving school = +1 *SD* from mean, low-achieving school = −1 *SD* from mean. AAs = African Americans.

students in high-achieving non-Hispanic schools is significantly different from the others, indicating that Mexican students in these schools, on average, experience the greatest social costs with achievement.

Other Hispanic ethnic groups were also considered across school contexts. Findings for Puerto Rican, Central or South American, and Cuban adolescents were, however, quite different. The percentage of Hispanic students was found not to influence the social costs of achievement for any of these groups. Furthermore, school-level achievement did not lead to increased social costs for any of these groups, regardless of whether or not the school was high achieving. In fact, for Puerto Rican and Central or South American adolescents school-level achievement was associated with lower social costs (more social acceptance) with achievement (GPA × Puerto Rican × SchAchieve: $B = .196$, $SE = .099$, $p < .05$; GPA × Central or South American × SchAchieve: $B = .124$, $SE = .045$, $p < .01$).

In additional analyses, the relation between achievement and social acceptance was considered for Black students as a function of the percentage of Hispanic students in the school and vice versa. No significant effects were found in these models, suggesting the importance of same-race minority peers, as opposed to minority peers in general. School context effects were also considered for Asians, but no significant differences were found. The percentage of White students in a school was also explored, but was not found to influence the effects of achievement on social acceptance for any of the groups considered.

Discussion

The current study explored the association between achievement and social acceptance across ethnic groups to test the proposition that some minority groups experience greater social costs with academic success. Furthermore, the effects of school-level variables on the relation between achievement and social acceptance were examined. To our knowledge, this study is the first to quantitatively demonstrate differential social costs with academic success across ethnic groups. In particular, results suggest that, as compared with Whites, Black and Native American adolescents experience more social costs with achievement, even after controlling for individual- and school-level disadvantage. These findings are in line with work

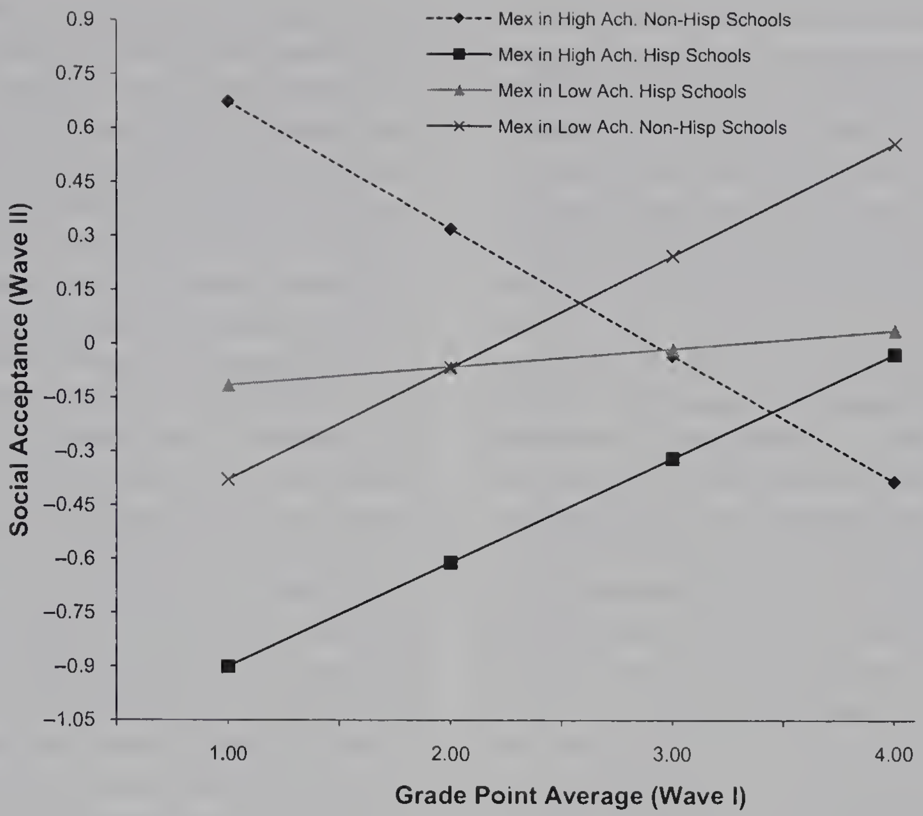

Figure 3. Fitted interaction plot depicting the relation between Wave I grade point average (GPA) and Wave II social acceptance for adolescents from Mexican descent in four school contexts.

Note. This figure is based on parameter estimates from Model 15, with GPA converted back to its original 4-point scale. Seventy-seven percent of Mexican students ($n = 689$) are in Hispanic schools (top quartile of percent Hispanic), and 23% ($n = 207$) are in less Hispanic schools. As school-level achievement is a continuous variable, specific sample sizes cannot be associated with each of the lines: high-achieving school = +1 *SD* from mean, low-achieving school = −1 *SD* from mean. Mex = adolescents from Mexican descent.

suggesting that greater social consequences may exist among currently stigmatized and historically oppressed groups (Fordham & Ogbu, 1986; Spencer & Harpalani, 2008; Steele, 1998).

An additional focus was to consider school-level contingencies. In particular, on the basis of existing work (e.g., Goldsmith, 2004), we explored school-level achievement and the proportion of same-race students in a school as moderators of the relation between achievement and social acceptance. Findings suggested that the social costs of achievement were greater for African Americans in higher achieving schools, but only when these schools had a smaller proportion of Black students. Specifically, for Black students, the social consequences of achievement were most severe in higher achieving schools with fewer Black students. However, when schools did have a substantial percentage of same-race peers, the social costs were relatively low, regardless of the levels of achievement within the school (Figure 1).

Consistent with our hypotheses, these findings suggest that the social consequences of achievement for African Americans are largely contingent on context (Cross, 2003; Spencer et al., 2001) and therefore are not likely to be the result of a widespread cultural orientation in opposition to achievement. Furthermore, results are in line with research suggesting that interracial tensions are more pronounced in competitive or high-achieving contexts (Brewer & Kramer, 1985), as well as with work suggesting that it is important for minority students to be exposed to a significant number of same-race peers (e.g., Goldsmith, 2004).

Our findings demonstrate that the greatest social costs with achievement for African American students are present in high-achieving schools with a smaller proportion of Black students. However, the results also show that, for Black students in predominantly Black schools, the relation between achievement and social acceptance is still not positive (see Figure 2). This is in contrast to a positive association between achievement and social acceptance for the majority group found in this study, as well as in previous work (Chen et al., 1997; Wentzel, 1991, 2005). The lack of positive association between achievement and social acceptance for African American adolescents in predominantly Black schools therefore suggests there are still some social costs with academic success for these students, relative to the majority group. This finding could be interpreted as in line with previous qualitative work conducted in predominantly Black schools (e.g. Fordham, 1988; Fordham & Ogbu, 1986). However, because the relation between achievement and social acceptance is more negative in competitive contexts, situational factors seem to be an important driving force behind this relation.

The school-level findings for African Americans were also replicated for students from Mexican descent. Specifically, Mexican students experienced substantially more social costs in higher achieving schools, but only when these schools did not contain a substantial portion of Hispanic students (Figure 3). However, other Hispanic groups did not show equivalent trends. In fact, the percentage of Hispanic students in a school had no effects for the Cuban, Puerto Rican, or Central or South American groups. Additionally, school-level achievement had no effect for Cubans and had a different effect for adolescents from Puerto Rican and Central or South American descent than for Mexicans or Blacks. Specifically, higher achieving schools were associated with lower social costs for Puerto Rican and Central or South American adolescents.

While this diversity in the social consequences of achievement among Hispanic groups was not predicted, a range of work is helpful in explaining these effects. First, relating to Mexican Americans, a variety of research suggests that with respect to subordination and disenfranchisement, the history of Mexican Americans is in many ways similar to that of Black Americans (Lopez & Stanton-Salazar, 2001; Portes & Rumbaut, 2001), and that the two groups are often similar in their reactions to discrimination (Portes, 1990). Given these perspectives, it is not surprising that Mexicans show similar tends to African Americans across school contexts. Several explanations are possible for the lack of social costs with achievement observed for Cuban, Puerto Rican, and Central or South American students across any of the contexts considered. Researchers have suggested that adolescents of Cuban descent tend to show fewer academic adjustment problems than those of Mexican descent (Portes, 1999). Additionally, most Cubans in our sample also tended to be in schools with a substantial portion of Hispanic students. With respect to Puerto Ricans, researchers have argued that their legal status as U.S. citizens may lead to less stigmatization and less problematic achievement dynamics than adolescents of Mexican descent (e.g., Flores-Gonzalez, 1999). Future work will be needed to test the various potential mechanisms behind the differential social costs experienced by particular groups. Overall, our findings are in line with the idea that acculturation experiences vary substantially across the individual ethnic groups within the Hispanic pan-ethnic category.

The current study also tested the possibility that immigrant status may be accounting for differences in social costs. Results of these analyses suggested that adolescents whose families have been in the United States for multiple generations did not show any greater social costs than their more recent immigrant counterparts. These findings, therefore, failed to provide support to the idea that length of time in the United States accounts for differences in social costs across groups (Portes & Zhou, 1993; Spencer et al., 2003). Based on previous research (Graham et al., 1998; Osborne, 1997), an additional hypothesis of the current study was that African American men might show greater social costs than women. Findings, however, showed no gender effect for African Americans, or for any of the other ethnic groups. This suggests that gender is not playing a direct role in the link between achievement and social acceptance.

Limitations and Future Directions

Although the findings of this study suggest that differential social costs do exist for particular groups, it was not within the scope of this research to determine the detailed mechanisms for these effects. It will therefore be important for future studies to develop a more detailed understanding of group differences, especially in school contexts where discrepancies in social costs across groups were found to be most pronounced. Work in this area has suggested that some differences in achievement values are present during early adolescence (e.g., Graham et al., 1998). However, the role of peer attitudes and norms in the relation between achievement and social acceptance is less understood. It will therefore be useful for future work to explore these effects, as well as to examine contextual factors that may be influencing the achievement values of minority peer groups (e.g., stereotypes and discrimination from the majority group, or socialization messages from families and communities).

Another area of future research will be to explore the role of identity in the social costs of achievement. This is of particular importance given that racial and ethnic identity are thought to influence perceptions of racism, as well as its consequences.

Furthermore, as differences in social costs across ethnic groups may be the result of attitudes and norms within peer groups, network techniques, which aggregate the characteristics of peers (e.g., Kiesner, Cadinu, Poulin, & Bucci, 2002), will be necessary to test these effects. Contextual factors such as socialization and experiences with discrimination will also be important to consider—particularly in relation to their role as predictors of group identity (Hughes et al., 2006; Sellers & Shelton, 2003).

Finally, it is unclear from the current study whether the social consequences of achievement experienced by particular groups come from same-race peers, from members of the dominant group, or from elsewhere. Distinguishing the source of social consequences with achievement will therefore be an important issue for future studies to address. It will be helpful to consider the possibility that greater social costs experienced by particular groups are the result of increased hostility from the majority group at higher levels of achievement. Specifically, given that research suggests that Whites direct their prejudice unequally, as a function of individual characteristics (Kaiser & Pratt-Hyatt, 2009), it is plausible that White adolescents may feel particularly threatened when members of specific groups achieve academically and therefore may express more hostility toward high-achieving members of these groups. Future research will be necessary to distinguish these various possible sources of social costs.

Conclusion

In closing, we wish to emphasize that although our findings indicate that ethnic group differences do exist, it is by no means our intention to insinuate that such differences are set in stone. Quite the opposite: Our hope is that a more nuanced understanding of ethnic group differences, and the complex dynamics behind them, will stimulate actions to address these issues within education systems at multiple levels. Although many researchers have argued for a color-blind perspective, suggesting that ethnic issues are irrelevant when background and contextual factors are considered (e.g., Cook & Ludwig, 1997; Rothstein, 2004), results of the current study suggest strongly otherwise. An important implication of this article is therefore that to redress ethnic gaps in achievement, in addition to focusing on socioeconomic and structural problems, schools and communities will need to understand and address issues of race.

Furthermore, while our results suggest that schools with more same-ethnic peers may be protective, we do not wish to imply that segregated schools are a necessity for minority students to maintain healthy social relations alongside academic achievement. We feel that a more appropriate implication of these findings is that schools with characteristics associated with differential social costs should seek to develop a greater awareness of unacknowledged stereotypes and take additional measures to maintain healthy racial dynamics. Specifically, previous recommendations for school personnel to focus on earning and maintaining the trust of minority students and to create an environment of "identity safety" (Davies et al., 2005; Ogbu & Simons, 1998) may be of particular importance in high-achieving schools where stigmatized minority groups are a clear minority.

Children's Reasoning About Disclosing Adult Transgressions: Effects of Maltreatment, Child Age, and Adult Identity

Thomas D. Lyon and
Elizabeth C. Ahern
University of Southern California

Lindsay C. Malloy
University of Cambridge

Jodi A. Quas
University of California, Irvine

A total of two hundred ninety-nine 4- to 9-year-old maltreated and nonmaltreated children of comparable socioeconomic status and ethnicity judged whether children should or would disclose unspecified transgressions of adults (instigators) to other adults (recipients) in scenarios varying the identity of the instigator (stranger or parent), the identity of the recipient (parent, police, or teacher), and the severity of the transgression (''something really bad'' or ''something just a little bad''). Children endorsed more disclosure against stranger than parent instigators and less disclosure to teacher than parent and police recipients. The youngest maltreated children endorsed less disclosure than nonmaltreated children, but the opposite was true among the oldest children. Older maltreated children distinguished less than nonmaltreated children between parents and other types of instigators and recipients.

What happens when children witness adult transgressions? Do children believe that transgressions should be disclosed or do they believe that the acts should be kept secret? Are children's attitudes affected by adverse familial experiences? Do children's beliefs vary across age, different transgressor identities, types of transgressions, and the person to whom the transgression is reported? Although these questions are of considerable theoretical and practical interest, there is virtually no research examining the development of attitudes regarding disclosure of adult transgressions. This study examined those attitudes among 4- to 9-year-old maltreated children and nonmaltreated children of comparable socioeconomic status and ethnicity.

Several lines of research are relevant to understanding children's emerging attitudes about disclosing adult transgressions: (a) children's disclosure of maltreatment and the effects of maltreatment on children's attitudes; (b) children's attitudes about disclosing the transgressions of others, typically peers; (c) children's attitudes about lying and children's honest and dishonest behavior; and d) children's attitudes about authority and the validity of authoritative demands. Each is discussed in turn. To facilitate comparisons across studies, we refer to persons who commit misdeeds and may encourage transgression secrecy as instigators, and those to whom the child might disclose transgressions as recipients.

Disclosure of Childhood Maltreatment

A real-world example of childhood disclosure of adult transgressions concerns the disclosure of child abuse, and a small but important body of

---

Portions of this research were presented at the American Psychology-Law Society, Jacksonville, FL, 2008, and the third annual meeting of the Conference on Empirical Legal Studies, Ithaca, NY, 2008. Vera Chelyapov, Megan Donahue, Hilary Feybush, Laura Hinojosa, Ektha Aggarwal, Deanna Cano, Jennie King, Kathryne Krueger, Irma Escobar, Bruce John, Emily Kerr, Crystal Lara, Leah Manchester, Cindy Mekari, Deborah Ogbonna, Shadie Parivar, Megan Sim, and LeighAnn Smith assisted in data collection and coding. We are grateful for the support of the Presiding Judge of the Los Angeles County Juvenile Court, the Los Angeles County Department of Children's and Family Services, Los Angeles County Children's Law Center, the Children's Services Division of Los Angeles County Counsel, and the Los Angeles County Child Advocate's Office. Preparation of this article was supported in part by National Institute of Child Health and Human Development Grant HD047290-01A2 and a Doctoral Dissertation Fellowship from the National Science Foundation (SES-0720421).

research has examined the process of disclosure among child victims of abuse. Findings offer some insight into how the identity of the instigator and recipient may influence children's attitudes about disclosure and highlight the need to examine attitudes in both maltreated and nonmaltreated samples. Maltreated children are often instructed to keep abuse a secret (Bussey & Grimbeek, 1995; Lyon, 2002), and surveys of adults reporting that they were sexually abused as children have found that a majority report never having disclosed the abuse during childhood (Laumann, Gagnon, Michael, & Michaels, 1994).

For one, the relationship of the child to the instigator affects the likelihood that the child will disclose: Children are less likely to disclose abuse by parents than by strangers (London, Bruck, Wright, & Ceci, 2008; Lyon, 2010). Furthermore, parents (typically mothers) are usually the first recipients when children disclose abuse (Anderson, Martin, Mullen, Romans, & Herbison, 1993; Fleming, 1997), especially among children younger than 10 years of age (Hershkowitz, Lanes, & Lamb, 2007; Kogan, 2004). Parental support has been shown to have an effect on the likelihood that children report abuse (Lawson & Chaffin, 1992), delay reporting (Hershkowitz et al., 2007), or maintain their report over time (Malloy, Lyon, & Quas, 2007).

Abuse by parents is less likely than abuse by strangers to be reported to the police (Hanson, Resnick, Saunders, Kilpatrick, & Best, 1999). Indeed, disclosure of sexual abuse to any official authorities (e.g., police or social workers) is quite rare; respondents in adult surveys state that only about 10% of abuse was reported to authorities (Mullen, Martin, Anderson, Romans, & Herbison, 1993; Russell, 1983; Smith et al., 2000).

If these patterns reflect children's reasoning about disclosure, the findings suggest that children will endorse more disclosure of wrongdoing to parents than to the police or teachers, particularly when the instigator is another parent. However, the low rates of disclosure to authorities may reflect caretakers' attitudes about disclosure rather than children's, since caretakers are most likely to control the decision regarding whether to report the abuse. Indeed, the extent to which children disclose to parents rather than others may simply reflect children's dependency on their parents rather than a clear preference for their parents as recipients.

The attitudes of maltreated children are of special interest, given the importance of maltreatment disclosure and the potential that maltreatment itself affects children's attitudes about transgression secrecy. Maltreated children have been found to make similar moral judgments as nonmaltreated children (Smetana, Daddis, et al., 1999; Smetana, Kelly, & Twentyman, 1984; Smetana, Toth, et al., 1999). For example, when asked about transgressions, both maltreated and nonmaltreated young children tended to classify moral violations (physical harm, psychological harm, or inequities in resources) as "very bad" and social conventional violations (disobeying school rules) as "a little bad" (Smetana et al., 1984). However, maltreated children are more likely to expect that others, including caretakers, will behave in unsupportive, rejecting, or punitive ways (Macfie et al., 1999; Shields, Ryan, & Cicchetti, 2001; Shipman & Zeman, 2001; Shipman, Zeman, Fitzgerald, & Swisher, 2003; Toth, Cicchetti, Macfie, Rogosch, & Maughan, 2000).

If children's expectations of the reactions of others affect their reasoning about disclosure, then maltreated children may reason differently about the disclosure of adult transgressions than nonmaltreated children. On the one hand, fears of the instigator and distrust of the recipient may make them less inclined to endorse disclosure in general. On the other hand, their negative attitudes about parents may make them less protective of parents and thus less likely to distinguish between stranger and parent instigators when endorsing disclosure.

Children's Age-Related Attitudes About Disclosing Transgressions

Although a few studies have examined children's developing attitudes about reporting wrongdoings, findings are inconsistent. Some research suggests that children are less likely to endorse disclosure of wrongdoing with age: Whereas most 5- to 6-year-olds endorsed disclosure, 8- to 10-year-olds were more inclined to endorse secrecy (Piaget, 1932; Watson & Valtin, 1997). Other research, however, suggests the opposite: increased disclosure endorsement with age. An unpublished study by Wilson and Pipe (reported in Pipe & Goodman, 1991) found that 9-year-olds were more likely to endorse disclosure of accidental breakage of a toy than 6-year-olds, and Rotenberg (1995) found some evidence that 9-year-olds were more likely than younger children to endorse disclosure of their own transgressions.

One reason for the variable results concerns the identity of the instigator. In studies finding decreased disclosure endorsement with age, the instigator was always a peer (either a brother, Piaget, 1932; or friend, Watson & Valtin, 1997). The age-related decrease could be owing to increasing protectiveness of peers, akin to children's greater dependency on peer relationships as they approach adolescence (Buhrmester & Prager, 1995; Hunter & Youniss, 1982). In contrast, research that found increased endorsement of disclosure in this age range either left the instigator unspecified (Pipe & Goodman, 1991) or identified the child herself as the instigator (Rotenberg, 1995). Children might judge disclosure of adult transgressions quite differently. Similarly, the research has generally failed to vary the identity of the recipient. With the exception of Watson and Valtin (1997), who found that children were more likely to endorse disclosure to a mother than a friend, the identity of the recipient was either unspecified (e.g., ''adults''; Rotenberg, 1995; Pipe & Goodman, 1991) or a parent (Piaget, 1932). Because children's attitudes may differ depending on the identity of the instigator and recipient, it is essential to evaluate the effects of such identities directly as well as in conjunction with children's age and maltreatment status.

Children's Attitudes About Obedience to Authority

Developmental changes in children's beliefs about obedience to authority may further influence their beliefs about disclosing transgressions. Young children, for example, may view disclosure of adult transgressions as an act of disobedience, particularly if the transgressor instructs them not to disclose. Piaget (1932) found evidence that before about 8 years of age, children are ''moral realists'' and believe that ''any act that shows obedience to a rule or even to an adult, regardless of what he may command, is good'' (p. 111). Subsequent research has questioned Piaget's conclusions, finding that children at all ages judge that authoritative adults cannot justly order children to engage in conduct that is clearly harmful to the child or others (Damon, 1977; Laupa & Turiel, 1986). The difference in results may partly be attributable to the types of conduct studied; whereas Piaget's scenarios concerned the principle of equality of duties (children sharing equally in chores), subsequent research has examined more serious transgressions, such as stealing (Damon, 1977) or physical fighting (Laupa & Turiel, 1986).

If children do not view secrecy about wrongdoing as unambiguously immoral, their attitudes may be more subject to authoritative commands. Indeed, when children as young as 4 have been questioned, nontrivial percentages will state that parents and teachers can order children to behave immorally, both with respect to lying (Laupa, Turiel, & Cowan, 1995) and fighting (Laupa, 1994). Hence, if young children in particular view nondisclosure as deferential to authority, then one would expect these children to be more reluctant to endorse disclosure, whereas with age, children's disclosure endorsement should increase.

Children's Attitudes About Lying

In contrast to the scant research on children's attitudes about transgression secrecy, a substantial amount of research has examined children's attitudes about lying. By at least 4 years of age, children believe that lying is wrong (Bussey, 1992; Peterson, Peterson, & Seeto, 1983) and are more critical of lies that conceal transgressions than white lies (lies not intended to do harm; Bussey, 1999; Peterson et al., 1993), and these attitudes do not change with age. Maltreated children develop similar attitudes (Lyon & Dorado, 2008; Lyon & Saywitz, 1999), and there is some evidence that young maltreated children are more sensitive than nonmaltreated children to the wrongfulness of lying (Lyon, Carrick, & Quas, 2010).

However, most research to date has concerned children's attitudes about concealing self-transgressions or other children's wrongdoing. In one of the few studies that investigated children's attitudes about lying for adults, Wagland and Bussey (2005) asked 5- to 10-year-olds to predict whether a child witnessing an adult friend commit a transgression would lie to his or her father. Although children's predictions of honesty were influenced by whether the father reassured the child that punishment was not forthcoming or emphasized the advantages of telling the truth, children never showed a tendency to predict lying, even in scenarios in which the child was implicated in the wrongdoing, the adult friend warned against disclosure, and the father emphasized the fact that the child would be punished.

Wagland and Bussey (2005) did not vary the identity of the instigator or the recipient. The instigator was always an adult friend and the recipient was always the child's father. Yet, there are several reasons to suspect that instigator and recipient identities would play a role in influencing children's attitudes about lying. For one, children are more likely to lie for a parent than for a stranger (Tye, Amato, Honts, Devitt, & Peters, 1999). Instigator warnings increase children's willingness to lie (Bussey, 1993). Second, although recipient identity has not been manipulated, recipient actions can increase honesty, such as by eliciting a promise to tell the truth (Lyon & Dorado, 2008; Lyon, Malloy, Quas, & Talwar, 2008; Talwar, Lee, Bala, & Lindsay, 2002, 2004), reassuring the child that disclosure will not get the child into trouble (Lyon & Dorado, 2008; Lyon et al., 2008), and discussing the importance of truthfulness (Huffman, Warren, & Larson, 1999; London & Nunez, 2002). Recipient identity may play a role in children's endorsement of transgression disclosure to the extent that children expect different reactions from different types of recipients.

However, it is unclear whether findings concerning children's honest and deceptive behavior are directly applicable to children's attitudes about transgression disclosure. Children may reason about secrecy differently than they reason about lying. Secrets, unlike lies, constitute omission of the truth rather than commission of a falsehood. Ethicists have noted that although one might maintain that lies are presumptively immoral, one cannot make the same claims about secrecy (Bok, 1982). Furthermore, research on children's lying behavior may not reflect children's reasoning: Children's behavior is likely the product of both deliberation about the morality of lying and the weighing of other factors (such as the likelihood of detection and punishment; Pipe & Wilson, 1994). Nevertheless, the research on children's attitudes about lying suggests that children will be more inclined to endorse disclosure of wrongdoing when the instigator is a stranger, and when the recipient is a person they trust, such as a parent.

Present Study

The purpose of this study was to examine maltreated and nonmaltreated children's attitudes about adult transgression secrecy. We presented 4- to 9-year-old children with and without a history of substantiated child maltreatment with scenarios involving one adult "instigator" (an adult wrongdoer who demands secrecy) and one adult "recipient" (an adult to whom the disclosure might be made). We varied the identity of the instigator (parent or stranger) and the identity of the recipient (parent, police, or teacher). We also varied the severity of the transgression, describing the adult's actions as "just a little bad" or "really bad." We left the acts unspecified to avoid variability in children's responses to specific factual scenarios, although, consistent with prior work (Smetana et al., 1984), we expected children to understand that the actions, particularly those that were "really bad," constituted moral violations. Finally, we varied whether children were asked if the story child "should" or "would" disclose the wrongdoing, to uncover potential differences between judgments about the morality of disclosure (as revealed by what "should" occur) and attitudes about the actual likelihood of disclosure (as revealed by what "would" occur).

Several hypotheses were advanced. First, with respect to maltreatment, we hypothesized that maltreated children would endorse less disclosure overall than nonmaltreated children because of their expectation that adults are unsupportive. We also predicted maltreated children would discriminate less among different types of instigators and recipients because they would be less inclined to view parents as deserving of special consideration or trust. Second, given the inconsistent age differences in former studies, we tentatively predicted that older children would endorse more disclosure of adult transgressions than younger children because of children's diminishing deference to authority.

Third, with respect to the child's relationship to the instigator and recipient, we predicted that children would be more likely to endorse disclosure against strangers than parents, and more likely to endorse disclosure to parents than police and teachers. We also expected to see some evidence of keeping disclosure within the family (so that there would be an interaction between instigator and recipient: Parent–parent disclosure would be endorsed more often than parent–nonparent disclosure). Fourth, we expected children to endorse more disclosure when asked what the story child "should" do than when asked what the story child "would" do because the former would elicit children's moral judgments whereas the latter might elicit attitudes about behavior influenced by more than morality (such as consequences). Fifth, we expected children to endorse more disclosure when the transgression was described as "really bad" rather than "just a little bad" analogous to children's differentiation of white lies versus harmful lies (Bussey, 1999; Peterson et al., 1993), and of violations of social convention versus moral violations (Smetana et al., 1984).

Finally, we advanced several predictions concerning children's explanations for their responses concerning transgression disclosure. Specifically, we expected that, in general, children's explanations would track their patterns of disclosure endorsement. Accordingly, for children who endorsed disclosure, we predicted that there would be more references to the instigator in the stranger than parent instigator stories (because the identity of the instigator would justify disclosure in the stranger stories) and the opposite pattern for children who endorsed nondisclosure. With respect to transgression severity, we expected that children who endorsed disclosure would mention the transgression more often when the transgression was ''really bad'' than when it was ''just a little bad,'' and the opposite pattern for children who endorsed nondisclosure. We further expected that children would refer more often to the instigator's command (don't tell) when endorsing nondisclosure than when endorsing disclosure.

Method

Participants

The sample consisted of two hundred ninety-nine 4- to 9-year-old maltreated ($N = 153$) and nonmaltreated children ($N = 146$; $M = 6$ years 7 months, $SD = 1.71$; 54% girls). The sample was ethnically diverse (62% Latino, 27% African American, 6% Caucasian, 5% Other). The maltreated sample consisted of children substantiated as suffering from child neglect and/or physical or sexual abuse who had been removed from the custody of their parents or guardians. Children gave their assent to participate, and consent was obtained from the Presiding Judge of Juvenile Court and the Children's Law Center, which represents children in dependency proceedings. Children were not eligible if they were awaiting an adjudication hearing or a contested disposition hearing on the date of testing (because they might be asked to testify), if interpreter services were provided to their family and they were clearly incapable of communicating with the researchers in English, or if their attorney had objected to their participation. The nonmaltreated sample consisted of children recruited from schools serving predominantly low-income ethnic minority families in neighborhoods comparable to those from which most maltreated children were removed. Children in the nonmaltreated sample who were not in the custody of one or both parents were excluded because of the potential that they had been removed from their parent's care because of maltreatment.

Materials and Procedures

Rapport building. The experimenter first built rapport with the child using questions adapted from those described in the National Institute of Child Health and Human Development Investigative Interview Protocol (Lamb, Hershkowitz, Orbach, & Esplin, 2008; Orbach et al., 2000). The child was asked about things he or she liked and did not like to do.

Disclosure vignettes. The experimenter read 20 brief vignettes (accompanied by pictures of characters) in which an adult (instigator) committed a misdeed and told a story child not to disclose. The story child was then depicted with a different adult (recipient) and the experimenter asked the child if the story child ''should'' or ''would'' tell the recipient what the instigator did, and then asked for an explanation. A sample vignette is:

> Here is a boy. Here is his dad. His dad did something really bad. The dad says to the boy, ''Don't tell.'' Now the boy is with his mom. Should the boy tell his mom what his dad did? Why?

The gender of the story child always matched the gender of the subject. Within subjects, the scenarios varied with respect to the instigator's identity (father, mother, or stranger, the latter defined as ''someone [the story child] does not know''), the recipient's identity (father, mother, police officer, or teacher), and the severity of the wrongdoing (''really bad'' or ''just a little bad''). These were fully crossed except that there were no vignettes in which the instigator and the recipient were the same (e.g., no father instigator–father recipient vignettes). The order of scenario administration was counterbalanced. Half of the children heard vignettes asking what the story child ''should'' do and half heard vignettes asking what the story child ''would'' do.

Verbal ability. At the end of the procedure children were administered the Productive Vocabulary subsection of the Woodcock–Johnson Psycho-Educational Battery–Revised: Tests of Cognitive Ability (WJ–R; Woodcock & Johnson, 1989) to assess verbal ability.

Results

Comparability of Maltreated and Nonmaltreated Children

The maltreated and nonmaltreated children were comparable in age (maltreated: $M = 6$ years 8 months, $SD = 1.60$; nonmaltreated: $M = 6$ years 5 months, $SD = 1.81$), $t(297) = 1.30$, $p = .165$; gender composition, $\chi^2(1) = 0.103$, $p = .748$; and productive vocabulary as assessed by the Woodcock–Johnson (maltreated: $M = 23.92$, $SD = 4.0$, mental age equivalent = 5 years 7 months; nonmaltreated: $M = 24.15$, $SD = 4.0$, mental age equivalent = 5 years 8 months), $t(285) = 0.49$, $p = .627$. The maltreated and nonmaltreated children were also comparable in percentages of Latinos (maltreated: 64%, nonmaltreated: 59%), $\chi^2(1) = 0.84$, $p = .360$, and Caucasians (maltreated: 8%, nonmaltreated: 4%), $\chi^2(1) = 1.84$, $p = .175$. However, a somewhat lower percentage of maltreated children were African American (maltreated: 22%, nonmaltreated: 33%), $\chi^2(1) = 4.26$, $p = .039$.

Disclosure Endorsement

We first analyzed whether children endorsed disclosure or nondisclosure and then analyzed their explanations for their endorsement. Children received a 1 for a *yes* response (endorsing disclosure) and a 0 for a *no* response (endorsing nondisclosure). Only 1% of responses were not codable as *yes* or *no* (*don't know*, unscorable). These are not considered further.

Preliminary analyses revealed no main effects or two-way interactions because of ethnicity, gender, or verbal ability, and these factors were excluded from subsequent analyses. Moreover, children did not discriminate between mother and father instigators or mother and father recipients. We thus collapsed across mothers and fathers to create mean scores for each child for parent instigator and parent recipient.

Omnibus analysis. The means across maltreatment status and age for instigator identity, recipient identity, and instigator–recipient scenario are presented in Tables 1 and 2. Preliminary analyses showed that the effects of the should–would ("should" the child tell vs. "would" the child tell) and transgression severity ("really bad" vs. "just a

Table 1

Proportions (SD) of Disclosure Endorsement to Different Instigators and Recipients, by Age and Maltreatment Status

	Instigator conditions		Recipient conditions			
	Parent	Stranger	Police	Parent	Teacher	Grand mean
4–5 years						
Maltreated	.53 (0.44)	.55 (0.42)	.56 (0.44)	.56 (0.44)	.54 (0.44)	.54 (0.43)
Nonmaltreated	.71 (0.34)	.77 (0.33)	.73 (0.35)	.76 (0.33)	.68 (0.35)	.73 (0.32)
6–7 years						
Maltreated	.54 (0.39)	.64 (0.41)	.63 (0.41)	.61 (0.41)	.49 (0.43)	.58 (0.38)
Nonmaltreated	.49 (0.39)	.62 (0.36)	.61 (0.39)	.63 (0.37)	.36 (0.39)	.54 (0.34)
8–9 years						
Maltreated	.60 (0.30)	.79 (0.26)	.74 (0.27)	.73 (0.30)	.53 (0.36)	.67 (0.26)
Nonmaltreated	.42 (0.34)	.77 (0.25)	.54 (0.30)	.67 (0.28)	.42 (0.32)	.56 (0.26)

Note. "Disclosure endorsement" refers to answering "yes" to "should s/he tell" or "would s/he tell."

Table 2

Proportions (SD) of Disclosure Endorsement to Different Instigator–Recipient Pairs, by Age and Maltreatment Status

	Instigator–recipient pairs					
	Parent–police	Stranger–police	Parent–parent	Stranger–parent	Parent–teacher	Stranger–teacher
4–5 years						
Maltreated	.56 (0.45)	.56 (0.46)	.54 (0.47)	.54 (0.44)	.49 (0.44)	.57 (0.46)
Nonmaltreated	.71 (0.39)	.77 (0.36)	.75 (0.38)	.80 (0.34)	.66 (0.38)	.69 (0.36)
6–7 years						
Maltreated	.60 (0.42)	.67 (0.44)	.57 (0.43)	.66 (0.43)	.46 (0.44)	.56 (0.47)
Nonmaltreated	.53 (0.43)	.76 (0.40)	.57 (0.43)	.68 (0.40)	.36 (0.43)	.37 (0.47)
8–9 years						
Maltreated	.66 (0.36)	.91 (0.24)	.70 (0.36)	.76 (0.34)	.44 (0.42)	.72 (0.38)
Nonmaltreated	.38 (0.40)	.86 (0.30)	.56 (0.38)	.80 (0.28)	.32 (0.37)	.62 (0.40)

Note. "Disclosure endorsement" refers to answering "yes" to "should s/he tell" or "would s/he tell."

little bad'') manipulations were limited to specific age groups, and those effects are discussed next. To test the study's main hypotheses, we conducted a 2 (maltreatment) × 3 (age: 4–5, 6–7, 8–9) × 2 (instigator: parent, stranger) × 3 (recipient: parent, police officer, teacher) mixed model analysis of variance (ANOVA).

Two significant main effects emerged: instigator, $F(1, 292) = 79.77$, $p < .001$, partial $\eta^2 = .22$, and recipient, $F(2, 292) = 58.86$, $p < .001$, partial $\eta^2 = .22$. Children endorsed lower rates of disclosure against parents ($M = 0.55$, $SD = 0.37$) than strangers ($M = 0.69$, $SD = 0.35$), and endorsed lower rates of disclosure to teachers ($M = 0.50$, $SD = 0.39$) than parents ($M = 0.67$, $SD = 0.36$) or the police ($M = 0.64$, $SD = 0.37$).

The effects of maltreatment and age were not significant, but several significant interactions emerged involving these variables. Specifically, maltreatment interacted with age, $F(2, 292) = 5.65$, $p = .004$, partial $\eta^2 = .04$; instigator, $F(1, 292) = 4.15$, $p = .043$, partial $\eta^2 = .01$; and recipient, $F(2, 292) = 5.17$, $p = .006$, partial $\eta^2 = .02$. Similarly, age interacted with instigator, $F(2, 292) = 23.21$, $p < .001$, partial $\eta^2 = .14$, and recipient, $F(4, 292) = 6.51$, $p < .001$, partial $\eta^2 = .04$. The two-way instigator and recipient interaction, reflecting differences across the six scenarios, was significant, $F(4, 584) = 7.69$, $p = .001$, partial $\eta^2 = .03$, as were the Instigator × Recipient × Maltreatment interaction, $F(2, 584) = 10.05$, $p < .001$, partial $\eta^2 = .03$, and the Instigator × Recipient × Age interaction, $F(4, 584) = 5.72$, $p < .001$, partial $\eta^2 = .04$.

To interpret these interactions, we examined age effects for maltreated and nonmaltreated children across the different instigator–recipient pairs, conducting one-way ANOVAs with age as the between-subjects factor. To reduce the likelihood of Type I errors, we used the Bonferroni correction (for 12 analyses) and set the critical p value at .004. For the maltreated children, only one type of story showed an age effect: Older children were *more* likely with age to endorse disclosure in the stranger–police scenarios, $F(2, 150) = 11.43$, $p < .001$, partial $\eta^2 = .13$. For the nonmaltreated children, older children were *less* likely to endorse disclosure in the parent–parent scenarios, $F(2, 143) = 9.64$, $p < .001$, partial $\eta^2 = .12$, and the parent–police scenarios, $F(2, 143) = 9.73$, $p < .001$, partial $\eta^2 = .12$. The nonmaltreated children also exhibited age effects for the parent–teacher scenarios, $F(2, 143) = 12.29$, $p < .001$, partial $\eta^2 = .15$, and stranger–teacher scenarios, $F(2, 143) = 7.59$, $p = .001$, partial $\eta^2 = .10$, which were attributable to decreases in disclosure endorsement to teachers by 6–7 years of age (a trend that was reversed in the stranger–teacher scenarios among the oldest children).

To summarize, children endorsed less disclosure against parent instigators than against stranger instigators, consistent with our predictions. Unexpectedly, children endorsed less disclosure to teachers than to either parents or the police. Neither maltreatment nor age had straightforward effects. Rather, maltreated children changed little in their endorsement of disclosure with age, except that they endorsed more disclosure with age in the stranger–police scenarios. Nonmaltreated children showed some evidence of decreased endorsement of disclosure with age, particularly when parents were instigators. To further understand the different patterns because of maltreatment status and age, we separately analyzed each age group.

Within age effects: 4- to 5-year-olds. Preliminary analyses revealed that the should–would manipulation (''should'' the child tell vs. ''would'' the child tell) affected children's responses at this age. A 2 (maltreatment) × 2 (instigator) × 3 (recipient) × 2 (should–would) ANOVA revealed significant effects of maltreatment, $F(1, 92) = 6.72$, $p = .011$, partial $\eta^2 = .07$; instigator, $F(1, 92) = 4.48$, $p = .04$, partial $\eta^2 = .05$; and recipient, $F(1, 184) = 4.61$, $p = .011$, partial $\eta^2 = .05$, and an interaction between should–would and instigator, $F(1, 92) = 11.42$, $p < .001$, partial $\eta^2 = .11$.

The main effect because of maltreatment was attributable to the fact that maltreated children ($M = 0.54$, $SD = 0.43$) endorsed lower rates of disclosure than nonmaltreated children ($M = 0.73$, $SD = 0.32$), $t(95) = 2.58$, $p = .011$. The main effect of instigator was because of children's greater endorsement of disclosure against strangers ($M = 0.66$, $SD = 0.39$) than parents ($M = 0.63$, $SD = 0.40$). This effect was qualified, however, by the interaction between instigator and should–would. It was only when asked what the child ''would'' do that children endorsed more disclosure against strangers ($M = 0.66$, $SD = 0.37$) than against parents ($M = 0.55$, $SD = 0.40$), $t(45) = 3.35$, $p = .002$. When asked what the child ''should'' do, children were equally likely to endorse disclosure against strangers ($M = 0.67$, $SD = 0.40$) as against parents ($M = 0.69$, $SD = 0.39$), $t(50) = 1.30$, $p = .201$. The main effect because of recipient was attributable to lower rates of endorsed disclosure to teachers ($M = 0.60$, $SD = 0.40$) than parents ($M = 0.66$, $SD = 0.40$), $t(96) = 3.36$, $p = .001$, or the police ($M = 0.65$, $SD = 0.40$), $t(96) = 2.30$, $p = .024$.

Together, these results suggest that, among the youngest children, nonmaltreated children endorsed more disclosure than maltreated children. Children endorsed more disclosure against stranger instigators than against parent instigators when asked what the story child "would" do but not when asked what the story child "should" do. Finally, children endorsed less disclosure to teachers than to police or parents.

6- to 7-year-olds. A 2 (maltreatment) × 2 (instigator) × 3 (recipient) ANOVA revealed significant main effects because of instigator, $F(1, 91) = 14.17$, $p < .001$, partial $\eta^2 = .13$; recipient, $F(1, 182) = 29.06$, $p < .001$, partial $\eta^2 = .24$; and an interaction between instigator and recipient, $F(2, 182) = 2.99$, $p = .053$, partial $\eta^2 = .03$. Maltreatment did not exhibit a main effect but interacted with recipient, $F(2, 186) = 4.53$, $p = .012$, partial $\eta^2 = .05$, and there was a three-way interaction among maltreatment, instigator, and recipient, $F(2, 186) = 5.23$, $p = .006$, partial $\eta^2 = .05$. To understand the interactions, we analyzed the different pairings of instigator and recipient separately (Table 2).

We had predicted that maltreated children would be less inclined than nonmaltreated children to protect parents as instigators or prefer parents as recipients. Therefore, we conducted a series of within-subject *t* tests in which we focused on comparisons between parents and nonparents. We first compared instigators (parents vs. strangers) for each type of recipient (parent, police, or teacher), and then compared recipients (parents vs. police) for each type of instigator (parent or stranger). Given the number of analyses (10), we adjusted the critical *p* value (.005). When the recipient was a police officer, only nonmaltreated children distinguished between parent and stranger transgressors, endorsing less disclosure against parents, $t(41) = 4.16$, $p < .001$. None of the other comparisons between parent and stranger instigators were significant (parent vs. strangers-teachers or parent vs. strangers-parents). Neither group of children exhibited a preference for parent over police recipients.

These results reveal that the 6- to 7-year-olds were, in some respects, similar to the younger children, endorsing more disclosure against strangers than against parents. However, there were no longer overall differences in endorsement of disclosure between nonmaltreated and maltreated children. Instead, nonmaltreated children began to discriminate more than maltreated children between parent and stranger instigators when talking to the police.

8- to 9-year-olds. Preliminary analyses revealed that the severity of the transgression ("really bad" vs. "just a little bad") affected children's responses at this age. Therefore, we conducted a 2 (maltreatment) × 2 (instigator) × 3 (recipient) × 2 (transgression severity) ANOVA. There were significant main effects of instigator, $F(1, 103) = 79.18$, $p < .001$, partial $\eta^2 = .44$, and recipient, $F(2, 206) = 26.33$, $p < .001$, partial $\eta^2 = .20$, and an interaction between instigator and recipient $F(2, 206) = 12.26$, $p < .001$, partial $\eta^2 = .11$. There were also main effects because of the severity of the transgression, $F(1, 103) = 18.06$, $p < .001$, partial $\eta^2 = .15$, and maltreatment status, $F(1, 103) = 5.32$, $p = .023$, partial $\eta^2 = .05$. The main effect for transgression severity was attributed to greater disclosure endorsement in response to "really bad" ($M = 0.66$, $SD = 0.27$) than "just a little bad" ($M = 0.57$, $SD = 0.29$) transgressions.

The main effect for maltreatment status reflected greater endorsement of disclosure among the maltreated children (Table 1). However, there was a three-way interaction among maltreatment, instigator, and recipient, $F(2, 206) = 4.07$, $p = .018$, partial $\eta^2 = .04$. Similar to the previous age group, we sought to understand the interactions by analyzing the different pairings of instigator and recipient separately, focusing on differences between parents and strangers as instigators and parents and police as recipients (Table 2). Again, because of multiple tests (10), the critical *p* value was set at .005.

When talking to the police, both maltreated and nonmaltreated children endorsed more disclosure against strangers than against parents—maltreated, $t(54) = 4.89$, $p < .001$, and nonmaltreated, $t(51) = 7.59$, $p < .001$—although the differences were larger for the nonmaltreated children. However, when talking to parents, only the nonmaltreated children were less likely to disclose against parents than against strangers: maltreated, $t(54) = 1.35$, $p = .183$, and nonmaltreated, $t(51) = 4.67$, $p < .001$. When deciding whether to disclose parental transgressions, only the nonmaltreated children preferred parent recipients to police recipients, $t(51) = 7.59$, $p < .001$. In contrast, when deciding whether to disclose stranger transgressions, only the maltreated children preferred police recipients over parent recipients: maltreated, $t(54) = 2.93$, $p = .005$, and nonmaltreated, $t(51) = 1.41$, $p = .17$.

To summarize the performance of the oldest children, they were the first to make distinctions on the basis of transgression severity ("just a little bad" vs. "really bad"). The maltreated and nonmaltreated children exhibited differences in their reactions to different instigator–recipient pairs, with the maltreated children sometimes exhibiting less deference to parental instigators and less preference for parental recipients than nonmaltreated children. Although both groups of children were more likely to endorse disclosure against strangers than against parents when talking to the police, the maltreated children were just as likely to endorse disclosure against parents as against strangers when another parent was the recipient. Finally, it is at 8–9 years of age when children first exhibited preferences for certain recipients given certain instigators. The nonmaltreated children preferred parent recipients when reporting on parent instigators, and the maltreated children preferred police recipients when reporting on stranger instigators. Hence, there was some evidence that the maltreated children were less deferential than nonmaltreated children to parental instigators and less likely to prefer parents as recipients.

Explanations

After children endorsed disclosure or nondisclosure, they were asked "why." We reliably coded children's explanations for whether they referred to various components of the scenarios, with the goal of identifying potentially significant concepts that could explain whether they selected disclosure or nondisclosure. Four primary categories were identified and children's responses could fall into more than one category: (a) instigator (e.g., "[Instigator] did not want him to tell"), (b) recipient (e.g., "[Recipient] will be able to solve it"), (c) transgression (e.g., "It's nothing important"), and (d) command (e.g., "[Instigator] said, 'Don't tell'"). We also coded for any reference to promising or secrecy, or to truth and lies to determine if children appeared to equate the scenarios with situations in which a child promises to keep a secret or lies. There were four coders (one gold standard coder and three research assistants). Based on 200 explanations, interrater agreement between the gold standard coder and the research assistants was 96%, with all Kappas exceeding .88. Discrepancies during the reliability coding were resolved through discussion.

We expected children's explanations to vary depending on scenario type and whether the child endorsed disclosure (i.e., answered "yes" or "no"). Because some children provided a mix of yes and no responses about disclosure to the different scenarios, whereas other children consistently responded "yes" or "no," the responses could not be appropriately analyzed either as between subjects or repeated measures; we therefore utilized a modified version of the t test that allows adjustment for the extent to which some responses are correlated within subjects (Looney & Jones, 2003).

We anticipated that whether children mentioned the instigator would depend on whether a stranger or a parent was the instigator and whether the child endorsed disclosure. We hypothesized that children who endorsed disclosure would reference the instigator more often in the stranger than parent instigator stories (because the identity of the instigator would justify disclosure in the stranger stories). This prediction was supported (corrected: $z = 4.04$, $p < .001$; stranger: $M = 0.67$, $SD = 0.34$; parent: $M = 0.60$, $SD = 0.35$). We expected that children who endorsed nondisclosure should reference the instigator more often in the parent than stranger instigator stories (because the identity of the instigator would justify nondisclosure in the parent stories). This prediction was also supported (corrected: $z = 2.34$, $p = .001$; stranger instigator: $M = 0.51$, $SD = 0.44$; parent: $M = 0.58$, $SD = 0.39$).

With respect to the mention of transgression, we expected that, if children endorsed disclosure, they would mention the transgression more often when the transgression was "really bad" than when it was "just a little bad." This prediction was not supported (corrected: $z = .54$, $p = .29$; really bad: $M = 0.33$, $SD = 0.36$; little bad: $M = 0.32$, $SD = 0.34$). If children endorsed nondisclosure, we expected the opposite; they would mention the transgression more often when the transgression was "just a little bad" than when it was "really bad." This prediction was also not supported (corrected: $z = .40$, $p = .66$; really bad: $M = 0.10$, $SD = 0.25$; little bad: $M = 0.10$, $SD = 0.22$).

Finally, with reference to the command category (in which children referred to the admonishment "don't tell"), we expected that this reference would occur more often when children endorsed nondisclosure than when they endorsed disclosure. This prediction was not supported, although the difference approached statistical significance (corrected: $z = 1.38$, $p = .08$; yes responses: $M = 0.08$, $SD = 0.22$; no responses: $M = 0.37$, $SD = 0.35$). Children only very rarely referred to promises or secrets (yes responses: $M = 0.02$, $SD = 0.09$; no responses: $M = 0.06$, $SD = 0.20$) or to truth and lies (yes responses: $M = 0.02$, $SD = 0.08$; no responses: $M = 0.01$, $SD = 0.07$).

The unexpected finding that children were less likely to endorse disclosure to teachers (noted earlier) led us to examine whether children who endorsed disclosure referenced the recipient more often in their explanations in the parent and police recipient stories than in the teacher recipient stories (because the identity of the recipient would justify disclosure in the parent and police stories), and whether children who endorsed nondisclosure would reference the recipient more often in the teacher recipient stories. No differences emerged in how often children who endorsed disclosure mentioned the recipient (corrected: $z = 1.17$, $p = .12$; parent/police: $M = 0.45$, $SD = 0.39$; teacher: $M = 0.47$, $SD = 0.41$). However, children who endorsed nondisclosure referred more often to the teacher recipient than to the parent or police recipient (corrected: $z = 3.01$, $p = .001$; parent/police: $M = 0.31$, $SD = 0.40$; teacher: $M = 0.41$, $SD = 0.39$).

In sum, some of our predictions with respect to explanations were borne out, especially when children endorsed nondisclosure (i.e., answered "no" to "should–would [the story child] tell"). Children distinguished between stranger and parent instigators in their reasoning about disclosure, and when endorsing nondisclosure, children distinguished between teachers and other recipients. Children only very rarely referred to promises or truth and lies, providing little evidence that they interpreted nondisclosure as a lie or the violation of a promise.

Discussion

This is the first study to examine maltreated and nonmaltreated children's attitudes about disclosure of adult transgressions varying the relationship of child to instigator (a transgressor who commands secrecy) and to recipient (an adult to whom the child might disclose). We examined a wide age range (4–9 years of age) and compared maltreated children to demographically similar nonmaltreated children. Our findings revealed that children's judgments were related to age and maltreatment in important ways. Moreover, the identity of the instigator and recipient affected children's willingness to endorse disclosure of adult transgressions. Each is discussed in turn.

Age and Maltreatment

Our inclusion of a wide age range and children with diverse maltreatment histories enabled us to consider developmental and experiential contributions to children's attitudes about transgression disclosure. We anticipated that children would be more inclined to endorse disclosure with age. Research on children's attitudes about obedience to authority suggests that unless a commanded act is unambiguously immoral, younger children tend to be more deferential than older children to authority (Laupa, 1994; Laupa, et al., 1995; Piaget, 1932). We thought that young children in particular would respond to the stories as if the instigator's admonition (don't tell) was an authoritative command, reducing their likelihood of endorsing disclosure. With respect to maltreatment, we suspected that maltreated children would anticipate more negative instigator reactions (and less supportive recipient reactions) and therefore endorse less disclosure overall. Across different instigators and recipients, we expected that maltreated children would be less inclined than nonmaltreated children to protect parents as instigators or prefer parents as recipients.

The results revealed that it was necessary to consider the effects of age and maltreatment together. The youngest maltreated children did in fact endorse less disclosure than the nonmaltreated children, but this difference disappeared among the 6- to 7-year-olds and was reversed among the 8- to 9-year-olds. Examining age differences within the two groups revealed that with respect to talking to the police, the maltreated and nonmaltreated children exhibited opposite age trends. The maltreated children were more inclined with age to disclose stranger transgressions. The nonmaltreated children, however, grew increasingly protective of parental instigators. As a result, older maltreated children were sometimes less likely than nonmaltreated children to distinguish between parents and strangers when deciding whether or not to endorse disclosure.

The finding that nonmaltreated children endorsed less disclosure against parent instigators with age appears most similar to findings that children over this age range endorse less disclosure when peers commit transgressions (Piaget, 1932; Watson & Valtin, 1997). Our findings suggest that attitudes about secrecy apply to child–parent relationships as well as child–peer relationships. The maltreatment differences may mirror findings that maltreated children have less faith in the supportiveness of parents than nonmaltreated children (Macfie et al., 1999; Shields et al., 2001; Shipman & Zeman, 2001; Shipman et al., 2003; Toth et al., 2000), which might explain why older maltreated children are not more protective of parent instigators than younger children.

Instigator Identity

Consistent with our prediction, children were less likely to endorse disclosure when the instigator was a parent rather than a stranger, and this pattern was confirmed by children's explanations. Even the 4- to 5-year-olds distinguished between parents and strangers, although these young children only endorsed less disclosure against a parent instigator when asked what a story child "would" rather than "should" do. This suggests that the youngest children were aware that disclosure is *less* likely against parents, whereas by 6–7 years of age, children both respond that one "would" and "should" disclose less against parents. Less endorsement of disclosure against parents is consistent with research examining children's actual disclosure of transgressions, both in experimental work on children's lies (Tye et al., 1999) and in observational research examining patterns of sexual abuse disclosure (Hanson et al., 1999; London et al., 2008; Lyon, 2009). Ours is the first study to demonstrate that these patterns are also reflected in children's attitudes.

Recipient Identity

The identity of the individual to whom the story child may disclose also affected children's responses, although in unexpected ways. Children endorsed less disclosure to teachers, and when they endorsed nondisclosure, they referred to the recipient more often in teacher recipient vignettes than when the recipient was a parent or the police. We suspect this is attributable to children's lacking understanding of the potential role of teachers in intervention; children may not be aware, for example, that teachers are mandated reporters of child abuse.

We predicted that children would generally be more inclined to endorse disclosure when the parent was a recipient. This prediction was not supported. Rather, preference for parental recipients emerged only in some scenarios and only among the oldest children. Moreover, this preference was limited to the nonmaltreated children, whereas maltreated children sometimes exhibited a preference for police recipients. The differences might reflect a relative lack of trust in parents among maltreated children.

Severity of the Transgression

Very few significant effects emerged regarding transgression severity. In fact, children did not take the severity of the transgression into account until they were 8–9 years of age. On the one hand, this may reflect the relative importance of instigators and recipients in children's judgments about transgression secrecy. On the other hand, it may be the case that children are influenced by the types of transgressions but that they require specific examples of those transgressions to make their judgments. In the future, it will be important to examine, using specific transgressions that vary in severity, whether and at what age children take severity into account when rendering decisions about disclosure.

Limitations

Although the findings reported here are novel and provide new insight into the combined effects of instigator and recipient relationships on maltreated and nonmaltreated children's emerging attitudes about transgression disclosure, limitations must also be acknowledged.

As a result of our interest in examining the relation between maltreatment and children's attitudes and because the research was located in a large urban area, our maltreated sample and comparable nonmaltreated sample were predominantly low income and of ethnic minority status. In contrast, prior research on children's attitudes about secrecy has tended to examine the attitudes of Caucasian children from middle- and upper-middle-class homes. Given the fact that this is the first study to examine children's attitudes about disclosure of adult transgressions, research is needed to examine whether the developmental differences observed here replicate more generally.

It might be the case, for example, that children with different backgrounds develop different attitudes about authority figures (e.g., police and teachers), and this could have influenced their judgments in the scenarios in which authority figures were the potential recipients. Indeed, there is considerable evidence that adolescents of ethnic minority status, particularly in low-income communities, tend to endorse negative attitudes about the police (Hurst & Frank, 2000; Sullivan, Dunham, & Alpert, 1987; Taylor, Turner, Esbensen, & Winfree, 2001) and that adolescents who endorse less positive attitudes toward the police also tend to endorse less positive attitudes toward other adults, including teachers and parents (Flexon, Lurigio, & Greenleaf, 2009; Nihart, Lersch, Sellers, & Mieczkowski, 2005).

However, there are hints in this research that participants in our study were less likely to be influenced by such attitudes. For one, we examined attitudes among elementary-aged children, a population that is not represented in the authority attitudinal research. The little developmental research that has been conducted suggests that the negative attitudes emerge as children move from preadolescence to adolescence. This may be because it is during adolescence when young people begin to attract the notice of police as potential suspects (Fagan & Tyler, 2005). Second, research on adolescents' attitudes tends to find that Latinos express less negative attitudes than African Americans (Sullivan et al., 1987; Taylor et al., 2001), and yet we found no ethnic differences in our sample. The dynamics between children's willingness to disclose to the police and other authorities in relation to children's attitudes about these professionals is clearly of interest in its own right and worthy of continued research.

Another limitation is that the scenarios did not specify what the adult instigator did; rather, we referred to the actions as "just a little bad" or "really bad." Scenarios were designed to leave the acts unspecified; this was because our primary interest was how children reasoned about disclosure given different instigators and recipients. We do not know whether children imagined specific content, and if so, what sort of actions they imagined. For example, children may have imagined moral acts of varying severity or as violations of social conventions. Of importance, however, several aspects of the task suggested that the transgressions reflected immoral acts. For one, the instigator gave the admonition "don't tell" to the child protagonist in every vignette and the police were included as potential recipients in a quarter of the vignettes (and, by the early school years, a majority of both maltreated and nonmaltreated children have at least a rudimentary understanding of the function of police; Cooper, Quas, Wallin, & Lyon, 2010). Also, prior work suggests that describing acts as "really bad," as was done in the current study, strongly connotes immoral behavior (Smetana et al., 1984). Future research can profitably explore whether children's attitudes about disclosure are in fact affected by the specific type of transgression. For example, we would predict that children will endorse disclosure of a peer's moral violation much more readily than they will endorse disclosure of a peer's violation of social conventions.

On a related note, differences in children's attitudes might have been attributed to children making different assumptions about the actions that different instigators performed. This seems unlikely, because transgression severity had minimal effects, both in terms of children's overall disclosure endorsements and their explanations for their responses. For example, children's explanations often included mention of identities of instigators and recipients without any mention of the transgression. If children were relatively insensitive to our explicit references to severity, one would not expect children to infer different actions that were described in an identical fashion across scenarios. Nevertheless, to address this concern future research could provide children more specific information about the transgressions in issue or inquire into children's assumptions about the transgressions that occurred.

Whether children's reasoning about the vignettes truly captures their reasoning with respect to their own decision making is of course subject to question, a problem that Piaget (1932) long ago recognized when questioning children about their moral judgments. One way to test this is to examine whether individual differences in children's reasoning predict differences in disclosure behavior. Research examining relations between children's attitudes about the morality of lying and honesty has tended to find low correlations (London & Nunez, 2002; Lyon, et al., 2008; Pipe & Wilson, 1994; Talwar et al., 2002). However, no research has examined the possible relation between children's attitudes about secrecy and their failure to volunteer information, as opposed to their attitudes about and proclivity toward lying. Examining individual differences in children's attitudes about transgression secrecy is also of interest in its own right; one could move toward understanding the underlying reasons for children's distinctions by searching for relations between children's attitudes about disclosure and other attitudes, such as the aforementioned trust in adults.

Future Directions

In examining children's attitudes about transgression disclosure, this study focused exclusively on adult instigators, given their obvious relevance to child maltreatment. But because the results suggest that nonmaltreated children's increasing protectiveness of their parents may parallel their attitudes about peers, future research should include both adult and peer instigators. Similarly, our assumptions that the patterns of disclosure endorsement are related to trust in adults, with trust in an instigator leading to less disclosure endorsement against that instigator and with trust in a recipient leading to greater disclosure endorsement to that confidant, are worthy of direct test. Although researchers have not explored the relation between trust and secrecy with respect to young children's relationship to their parents, researchers examining developing conceptions of friendship have noted such a connection (Rotenberg, 1991). Future work could explicitly test for links among children's expectations of adult supportiveness, adult reactions to disclosure, and their disclosure endorsement, and determine whether these links vary between maltreated and nonmaltreated children.

Future research might also assess the influence of other factors on children's attitudes about transgression disclosure. In this study, the instigator in the vignettes instructed the child not to tell. Whether this influenced children's judgments is unclear. If children based their judgments on their trust in the different adults involved, rather than fear of retribution, then the admonition may not have had an effect. Conversely, stronger language by the instigator might affect children's judgments. For example, explicit threats of punishment (or, in the case of parents, loss of love) might have an effect, as might explicit requests to keep the transgression a secret, or elicitation of a promise by the story child not to disclose. At the same time, it would be interesting to assess children's attitudes about various approaches that recipients might take to encourage disclosure.

Finally, future research with maltreated children might attempt to tease apart whether specific aspects of maltreatment influence children's judgments about transgression disclosure, including, for example, the effects of severity or type of maltreatment, children's relationship to the perpetrator, and the possibly confounding effects of state intervention. One might, for example, interpret the finding in our study that older maltreated children endorse more disclosure than nonmaltreated children as reassuring, because it suggests that children who experience maltreatment do not think that transgressions should be kept a secret. However, the maltreated children in this study were of necessity those children who had been identified as such by the state, and were extreme cases of maltreatment because the children had been removed from their parents' custody. It may be that children who suffer from isolated types of maltreatment (such as sexual abuse in an otherwise non-neglectful and nonabusive home) maintain positive attitudes toward transgression secrecy.

In conclusion, this study provides a first step toward an understanding of how children reason about disclosing the wrongdoing of adults, particularly those close to them. Theoretically, the findings contribute to our understanding of children's developing attitudes about the effect of social relationships on secrecy and the effects that adverse experiences may have on those attitudes. Practically, the results suggest that children's deference to parents may be a double-edged sword. Protectiveness of parents is surely a virtuous trait. In extreme circumstances, however, it may hinder society's ability to help children whose trust is misplaced.

Preverbal Infants Anticipate That Food Will Be Brought to the Mouth: An Eye Tracking Study of Manual Feeding and Flying Spoons

Olga Kochukhova and Gustaf Gredebäck
Uppsala University

This study relies on eye tracking technology to investigate how humans perceive others' feeding actions. Results demonstrate that 6-month-olds ($n = 54$) anticipate that food is brought to the mouth when observing an adult feeding herself with a spoon. Still, they fail to anticipate self-propelled (SP) spoons that move toward the mouth and manual combing actions directed toward the head. Ten-month-olds ($n = 54$) and adults ($n = 32$) anticipate SP spoons; however, only adults anticipate combing actions. These results suggest that goal anticipation during observation of feeding actions develops earlier and is less dependent on directly perceived actions than goal anticipation during observation of other manual actions. These results are discussed in relation to experience and a possible phylogenetic influence on perception and understanding of feeding.

One of the earliest goal-directed actions that we experience in our life is feeding. During the first months of life, a regular intake of food is of the highest priority to a young infant. In addition to providing necessary nutrients, it is an arena for comfort and social support, all of which are important aspects of early development. Infants generally start breastfeeding or drinking formula from a bottle. However, this early monopoly on liquids is quickly broken as solids are introduced. In fact, Lepage, Moisan, and Gaudet (2004), reported that 99.8% of Canadian 6-month-olds and 60% of 4-month-olds had been fed other types of food than breast milk; as many as 93.5% of the 6-month-olds had been given cereals. In a similar study, Traveras et al. (2004) reported that only 24% of all 6-month-olds were fed exclusively with breast milk.

In addition to engaging in feeding, young infants (from 3 to 6 months) often place objects inside their mouths, spending on average 4–20 min per day performing such actions (Juberg, Alfano, Coughlin, & Thompson, 2001). Over these months, infants develop substantial mouth–hand coordination. Starting at 5 months of age, infants anticipate their hand approach through predictive mouth opening (Lew & Butterworth, 1997). However, it is only at 9 months that infants start picking up spoons and placing them correctly in their mouths (McCarty & Keen, 2005). Jointly, the importance of feeding combined with infants' extensive hand–mouth coordination ensure that feeding (or placing objects inside one's mouth) is a special (and perhaps unique) class of actions. Despite this, surprisingly little is known about how infants perceive and interpret observed feeding actions (for an exception, see Gredebäck & Melinder, 2010). In contrast, recently, several studies have been published that pursue the development of action understanding during observation of others' manual actions (Falck-Ytter, Gredebäck, & von Hofsten, 2006; Flanagan & Johansson, 2003; Gredebäck, Stasiewicz, Falck-Ytter, Rosander, & von Hofsten, 2009).

Numerous studies have relied on eye tracking and anticipatory gaze shifts to investigate the connection between action production and action understanding in both adults and infants. These studies demonstrate that adults look at the goal of their own manual actions before they are completed (Johansson, Westling, Bäckström, & Flanagan, 2001; Land, Mennie, & Rusted, 1999; Lee, Yound, Reddish, Lough, & Clayton, 1993). Infants and adults also anticipate the goal of others' manual actions (Falck-Ytter et al., 2006; Flanagan & Johansson, 2003; Gredebäck et al., 2009). A recent illustration of this finding was reported by Falck-Ytter et al. (2006). In this study, 6- and

12-month-old infants, as well as adults, were presented with an actor who either placed toys inside a bucket or sat passively as the toys moved on their own to the bucket (the agent's head was not visible). The results indicated that 1-year-olds and adults looked at the bucket, before the toys arrived, but only when a human model moved the toys. Six-month-old infants were unable to anticipate the goal when the model moved the toys. The authors note that infants become increasingly proficient at placing objects inside containers between 6 and 12 months of age (Bruner, 1970) and argue that this experience drives the development of anticipatory gaze shifts.

These results are consistent with habituation studies emphasizing that both experience and the perception of a human agent are important for the ability to encode the goal of manual actions (Sommerville, Woodward, & Needham, 2005; Woodward, 1998, 1999; Woodward & Guajardo, 2002). For example, Woodward (1998) presented 5-, 6-, and 9-month-old infants with a model who reached for one of two toys. After habituation, the toys changed place and the model reached either for the same toy in a new location or for a new toy at the old location. All participants looked longer when the model reached for the new toy but not when the model reached along a new path getting the old toy. This selective attention to goals was only present during observation of human reaching and not when infants observed similar actions being performed by a mechanical claw. One factor that influences this enhanced goal processing is infants' own experience in performing the same task. This was demonstrated by Sommerville et al. (2005), who obtained results similar to Woodward (1998) with 3-month-old infants, when they were trained on a reaching task prior to habituation.

At the same time, by using habituation procedures, investigators have demonstrated that young infants are sensitive to the rationality of movement with a wide range of self-propelled (SP) objects (Csibra, 2008; Csibra, Bíró, Koós, & Gergely, 2003; Kamewari, Kato, Kanda, Ishiguro, & Hiraki, 2005). For example, in a recent study by Csibra (2008), 6.5-month-old infants were habituated to movies of SP boxes that moved past an obstacle to reach a goal (functional movement). After this habituation phase, the obstacle was removed. In these test trials, infants looked longer if the agent continued on the old, nonfunctional path but not if the agent changed to a new functional path to reach the goal. The results of this study are interpreted in favor of the teleological stance (Gergely & Csibra, 2003), suggesting that infants distinguish functional and nonfunctional events from each other based on how objects move relative to the environment. According to teleological stance perspective, action understanding is mediated by visual properties of the observed events, including the path taken by the moving entity and its relation to the goal. In addition, infants are sensitive to the rationality of observed events (e.g., the degree to which objects follow straight or optimal paths to reach a goal) and expect objects to move, and actions to be carried out, in a rational manner. These assessments are based on visual properties of perceived events and are neither dependent on one's own experience (performing the same action) nor require the presence of a human actor (see Gergely & Csibra, 2003; Kiraly, Jovanovic, Prinz, Aschersleben, & Gergely, 2003).

The findings by Falck-Ytter et al. (2006) and Woodward (1998) demonstrate that infants' experiences are important for their ability to encode and anticipate the goals of observed events. However, infants may rely on visual properties of the observed motion and the relation between the moving object and the goal (Gergely & Csibra, 2003). Given the solid empirical findings that exist in support of both these accounts it is unlikely that only one of these mechanisms is present and influences infants' understanding of others', actions. However, little is known about their relative importance for guiding anticipatory gaze shifts and how their relative importance changes over time.

This study attempts to enhance our understanding of how infants perceive and interpret actions performed by others. In addition, we strive to map out the relative importance of two processes (experience and the more experience-independent rationality assessments suggested by the teleological stance). Are infants' goal-directed gaze shifts *primarily* guided by experience with similar actions or by visual motion properties and the relation between the moving entity and the goal?

To answer these questions, we developed two experiments. In the first experiment, we present infants with normal feeding actions (an action that infants are well acquainted with) and feeding events that do not include a manual action (SP spoons). The second experiment presents infants with a different manual action, which holds similar motion characteristics as the feeding action (presented in Experiment 1), but in this case, the action was largely unknown to the infants (e.g., a model combing her hair). Both experiments record infants' gaze as they observe these events. Infants' ability to anticipate the current action goal was compared over conditions.

Experiment 1

Six- and 12-month-old infants as well as adults were presented with one of two videos featuring feeding actions. In one condition, the feeding action corresponded with participants' own experience (human feeding [HF] condition), whereas the other condition featured a novel feeding event that included the same goal but lacked the manual components required to perform the feeding task; in this case, the spoon moved on its own toward the mouth (SP condition). The assumption that goal anticipation during observation of manual actions is *primarily* driven by experience with similar tasks suggests faster goal fixations (more anticipations) during normal feeding compared to matched SP events. The alternative assumption, proposed by teleological stance theory, where goal anticipations are primarily guided by visual properties of the motion and its relation to the goal suggests equal goal fixation latencies to both manual feeding actions and SP spoons, because these properties are matched across conditions.

We included 6-month-olds because at this age, infants already have some experience being fed, and, at the same time, they fail to anticipate other manual actions (Falck-Ytter et al., 2006). In comparison to 6-month-olds, 12-month-olds have ample experience being fed, they are able to place spoons correctly into their mouth (McCarty & Keen, 2005), and anticipate other manual actions (Falck-Ytter et al., 2006). The novelty of this task warranted the inclusion of an adult control group to frame infants' development.

Method

Participants. Thirty-six 6-month-old infants (24 females, mean age = 187 days, *SD* = 8), thirty-six 10-month-old infants (16 females, mean age = 303 days, *SD* = 9), and 24 adults (13 females, mean age = 31.4 years, *SD* = 8) participated in Experiment 1. Eighteen infants were included in each experimental condition. All infants were from middle-class Caucasian families. Only 1 participant was excluded, a 10-month-old infant, because of fussiness. All infants were full-term and healthy. Mean experience with spoon-feeding in 6-month-old group was 1 month 7 days (*SD* = 14 days). Only three 6-month-old infants had no experience being fed with a spoon. All 10-month-olds had experience being fed with a spoon; mean experience with spoon-feeding equaled 5 months 12 days (*SD* = 21 days) and did not differ between conditions. Three 10-month-old infants in the SP condition and two 10-month-olds in the manual condition could successfully use a spoon to feed themselves.

Stimuli and procedure. All infants were recruited by mail, whereas adults were recruited from the university campus. All signed a consent form prior to participation and received a gift voucher (€14). The study was approved by the Regional Ethics Committee according to the 1964 Declaration of Helsinki.

Prior to participation, we asked parents several questions about their infant: (a) Do you feed your child with a spoon? (b) When did you start to feed your child with a spoon? and (c) Can your child put a spoon with food into her or his mouth (feed her- or himself successfully)? After these questions, infants were seated in a safety car seat on the parent's lap. Their gaze was measured with a Tobii 1750 (Stockholm, Sweden) near infrared gaze tracker system (subjects' eyes approximately 60 cm from the monitor). The camera records near infrared reflections of both eyes at 50 Hz (accuracy = 0.5°, spatial resolution = 0.25°) while the stimuli is presented on a 17-in. screen.

During the 9-point calibration phase, infants watched a blue-and-white sphere over a white-dotted black background (Gredebäck & von Hofsten, 2004) expand and contract (extended diameter = 3.3°) in synchrony with a sound. In cases where infants were inattentive, a small frame with a cartoon video was shown until infants attended again to the monitor. Following this calibration, participants were presented with a context movie (identical in both conditions) and one of two possible sets of experimental movies (each participant only viewed one set of experimental movies; i.e., they participated in only one condition).

During the context movie, a female peeled and cut a banana and placed its pieces on a plate (Figure 1a). Duration of the context movie was 29 s. This movie was followed by five identical condition specific movies. In the *HF condition*, these movies started with the actor looking into the camera for 1 s with her hands on her lap. The actor then turned her attention to the plate by turning her head and eyes to the plate while simultaneously lifting her arm to take the spoon from the table. After the spoon was picked up, the actor took a piece of banana from the plate, and brought it to

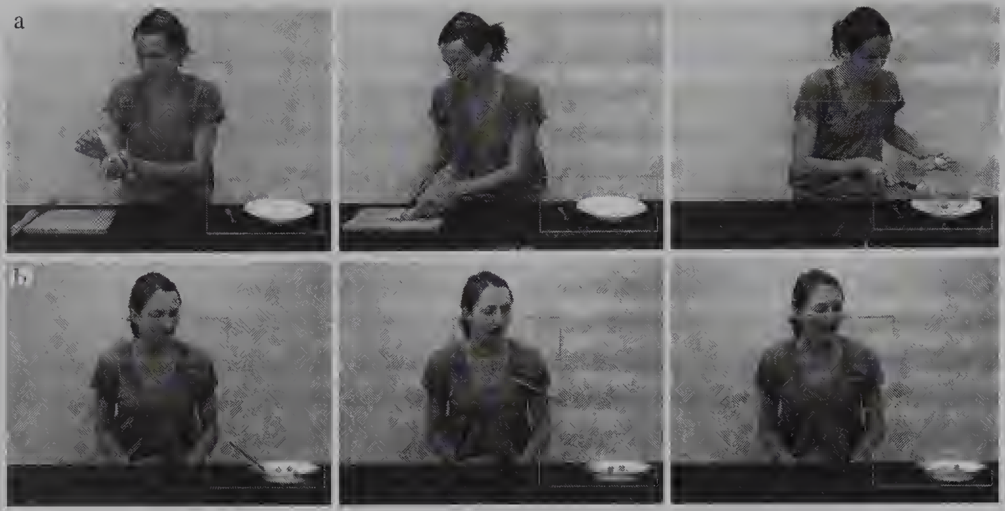

Figure 1. Snapshots from initial context movie (a) and the self-propelled (SP) condition (b). The upper rectangle (mouth area of interest [AOI]) covers the model's mouth, taking into account head movement during the movie; the lower rectangle depicts the location of the plate AOI.

her mouth. In the *SP condition*, the same sequence was repeated with the only exception being that the actor did not produce any manual actions; instead, the spoon flew by itself to the plate, took a piece of banana, and moved toward the actor's mouth (Figure 1b). In both conditions, the feeding action ended once the spoon had deposited the banana inside the actor's mouth and once the food had been eaten. Duration of each condition specific movie was 39 s; each movie included four feeding events (actions). Thus, each participant saw 20 feeding events during the experiment. The duration of the spoon's movement, trajectory of the spoon, the time when the model's mouth opened, and the location of the model's head were matched over conditions. All movies extended 22.5° × 19.5° of visual angle, the agent's head covered 4° × 5°, and the plate 4.3° × 1.7°. The angular distance between the plate and the mouth extended 14° and the vertical extent of the agent in the picture was 13°. The entire experimental session lasted no more than 5 min.

Data analysis. All analyses were performed using custom-made analysis programs in the Matlab (Mathworks Inc., Natick, MA) environment. Two areas of interest (AOIs) were defined (gray rectangles in Figure 1); one covered the starting position of the spoon (plate AOI) and one covered the area around the mouth of the actor (mouth AOI). Gaze was analyzed only during each spoon movement from the plate AOI to the mouth AOI. All AOIs had the same size and location; the mouth AOI covered the location of the mouth during all head movements performed by the actor. Participants' gaze shifts were included in the analysis only if subjects fixated the plate AOI for 200 ms (Gredebäck, Örnkloo, & von Hofsten, 2006), then shifted their gaze to the mouth AOI and fixated it for 200 ms, before the spoon left this area. Thus, participants could pay attention to the video sequence on a given trial and still be excluded from analysis, if attention was not directed to the feeding action (in accordance with the criteria mentioned before).

The timing of the infants' gaze shifts to the mouth AOI was compared to the time when the actor started to open her mouth after the spoon left the plate AOI. Gaze shifts above 0 were considered predictive, indicating that participants shifted their gaze to the mouth AOI before the actor started to open her mouth.

Results were analyzed through factorial analyses of variance (ANOVAs) with age (6-, 10-month-olds, and adults) and condition (HF and SP) as independent variables. Significant effects were further explored using Tukey honestly significant difference (HSD) post hoc tests. The degree to which the latency of participants gaze shifts differed significantly from 0 (separating predictive and reactive conditions) was estimated with Bonferroni corrected single-sample *t* tests.

Results

Six-month-old infants attended to feeding actions in 40% (*SE* = 5) of trials in the SP condition and in 42.5% (*SE* = 5) of trials in the HF condition. Mean amount of anticipations, made during these trials, was 37% (*SE* = 6) in the SP condition and 49% (*SE* = 6) in the HF condition. Ten-month-old infants and adults followed the feeding action in 52% (*SE* = 5) and 64% (*SE* = 6) of trials in the SP condition versus 46% (*SE* = 5) and 76% (*SE* = 6) of trials in the HF condition, respectively. Ten-month-olds evidenced anticipations on 45% (*SE* = 7) of attended trials in the SP condition and on 62% (*SE* = 6) of attended trials in the HF condition. For adults, these numbers equaled 62% (*SE* = 6) and 71% (*SE* = 6), respectively.

Preliminary tests did not indicate any order effect in either of the conditions ($p > .05$); data were therefore aggregated across presentation order. A factorial ANOVA with number of attended trials as the dependent variable demonstrated a significant main effect of age, $F(2, 90) = 14$, $p = .001$; post hoc tests differentiated the higher attention rates to the action in adults from attention rates in both 6- and 10-month-old infants ($p = .001$).

More important, the latency of participants' gaze shifts to the mouth during feeding actions differed depending on the age of the participant, $F(2, 90) = 6.3$, $p = .005$. Post hoc tests demonstrated that 6-month-old infants shifted their gaze to the model's mouth much later than 10-month-olds ($p = .006$) and adults ($p = .001$). Latencies also differed between the two conditions, $F(1, 90) = 7.5$, $p = .01$, with faster latencies during HF ($p = .005$). Single-sample *t* tests demonstrate that 6-month-olds predicted the goal of manual feeding actions, $t(17) = 3.6$, $p = .002$, but not SP feeding (*ns*). Ten-month-olds and adults anticipated the goal of feeding action during both manual, 10-month-olds: $t(17) = 4.2$, $p = .001$; adults: $t(11) = 4.8$, $p = .001$; and SP feeding, 10-month-olds: $t(17) = 3.8$, $p = .01$; adults: $t(11) = 3.6$, $p = .005$ (see Figure 2).

Discussion

Experiment 1 demonstrates that 6-month-old infants anticipate the goal of normal feeding actions and track SP spoons in a reactive manner. At the same time, all age groups showed faster goal fixation latencies to normal feeding than during observation of SP spoons. Two lines of evidence suggest that these differences can be related to the observers' own experience with similar tasks.

First, the fact that 6-month-olds anticipate normal feeding actions (but not SP spoons) supports the predictions derived from the experience account. According to this perspective, experience facilitates action understanding and goal anticipation of tasks that closely accord with the infants own experience. The fact that both 10-month-olds and adults demonstrated faster anticipations in the manual feeding condition compared to the SP condition suggests that the same general mechanism holds an influence on action understanding and goal anticipation throughout development. At the same time, this finding does not support the assumption proposed by the teleological stance theory that young infants rely predominantly on visual properties of the motion and its relation to the goal when observing ongoing manual actions.

However, there are differences between the manual and SP conditions (see also Falck-Ytter et al., 2006) that do not relate solely to the presence or absence of human actions and the familiarity of the task. In the manual feeding condition both the arm

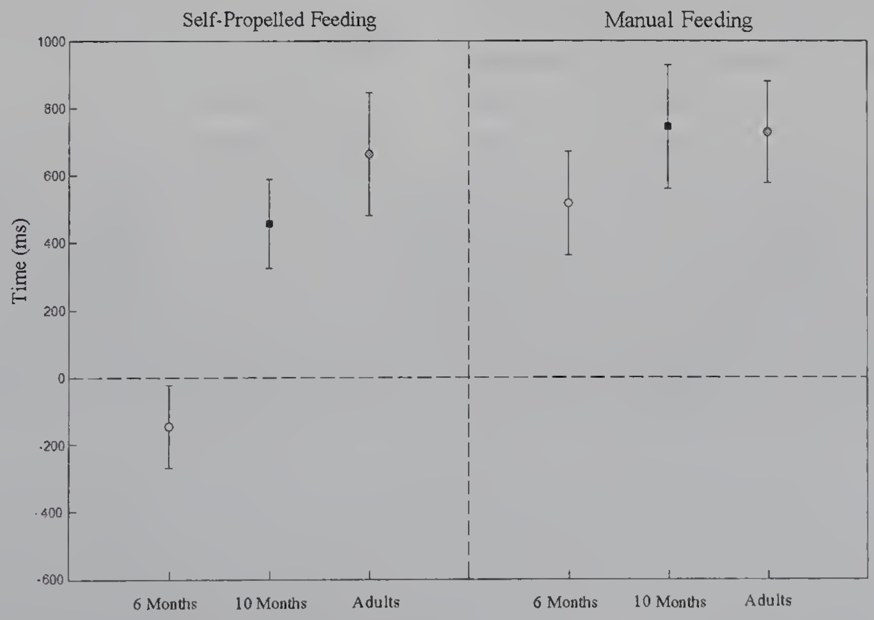

Figure 2. Gaze performance during observation of actions in both experimental conditions.
Note. Vertical axis depicts timing of gaze arrival at the mouth area of interest (AOI) relative to the time of actor's mouth opening during the action. The start of mouth opening is represented by the horizontal line at 0 ms. Positive values correspond to early arrival of gaze at the target area. Error bars represent standard errors of the mean.

and the spoon move, creating prominent motion cues in the direction of the goal, whereas the SP spoon provides the observer with a similar, but smaller, degree of motion. It is possible that this difference in visible motion is a mediating factor that influences the latency of goal-directed gaze shifts, with more predictions in response to large moving objects (HF condition) than during observation of a small moving object (SP condition). At the same time, it should be noted that arm movements alone are not sufficient to produce anticipatory gaze shifts. In a recent article, Gredebäck et al. (2009) demonstrate that infants only anticipate the goal of functional manual actions directed toward salient goals. Simply observing a moving hand, without a clear connection to a goal, did not result in anticipatory gaze shifts. Based on this finding, it is unlikely that the saliency of the movement is the sole cause of the differences reported in Experiment 1. However, the possibility still exists that motion becomes a mediating factor that adjusts the latency of goal-directed gaze shifts in the presence of a salient goal. We refer to this alternative account as the *degree of motion hypothesis*.

Second, the suggestion that action understanding (as measured by goal anticipations) is influenced by experience receives additional support through comparing the current findings to those obtained by Falck-Ytter et al. (2006). According to the literature reviewed in the Introduction (and the parental reports described in the Results section of Experiment 1), infants possess ample experience participating in manual feeding actions before 6 months of age. Manual containment actions (Falck-Ytter et al., 2006), however, are not readily performed by infants before they are 7–9 months of age (Bruner, 1970). Accordingly, 6-month-olds anticipate manual feeding actions but not containment actions. Goal anticipation of the latter action only occurs once infants have become proficient at placing objects inside containers at 12 months of age. It is tempting to attribute these differences in onset of anticipatory gaze shifts to infants' own experience with the specific task being observed. However, it is possible that goal saliency represents a mediating factor that differentiates the onset of anticipatory gaze shifts (between the two studies) irrespective of experience. According to this alternative account (referred to as the *saliency hypothesis*), young infants anticipate the goal of feeding actions from an early age because the human head is a highly salient goal whereas goal anticipation of manual containment actions emerges later because the goal of this action is less salient (a bucket).

Experiment 2 is designed to test both of these alternative hypotheses, by presenting 6- and 10-month-old infants and adults with a goal-directed manual action that only adults have experience performing, namely, combing. Manual combing actions provide the observer with motion information from the hand and the comb (serving as a control for the relative motion hypothesis). At the same time, combing actions are directed toward the head (providing a control for the saliency hypothesis). Both of these alternative hypotheses suggest that infants will be able to anticipate the goal of this manual action. However, if infants' own experience is the primary cause of action understanding and goal anticipation, we predict that only the adult group will be able to anticipate the goal of this action. This prediction is based on parental reports, indicating that infants' experiences with such tasks are limited (see the Participants section of Experiment 2).

Experiment 2

Experiment 2 presents 6- and 10-month-old infants, as well as adults, with movies of an adult human who picks up a comb and combs her hair. The main purpose of this experiment is to test the validity of the claim that experience mediates a strong influence on infants' action understanding and goal anticipations. To allow comparisons with Experiment 1, both the sequence of actions and the timing of each action were matched to the conditions presented in Experiment 1.

Method

Participants. Eighteen 6-month-olds (eight females, mean age = 184 days, *SD* = 5), an equal number of 10-month-olds (12 females; mean age = 304 days, *SD* = 9), and 8 adults (5 females; mean age = 29 years, *SD* = 7) participated in Experiment 2. Three additional 6-month-olds and 1 additional 10-month-old infant were excluded because of fussiness. All infants were full-term and healthy; the majority of families came from a Caucasian middle-class background. Parents of two 6-month-old infants and four 10-month-old infants reported that their children on occasion saw them comb their hair. None of the participating infants had experience combing their own hair.

Stimuli and procedure. The procedure in this experiment was the same as in Experiment 1 with one exception. Participants' gaze was measured with Tobii T120 near infrared gaze tracker system that records near infrared reflections of both eyes at 60 or 120 Hz sampling frequency as participants watched a 17-in. monitor (accuracy = 0.5°, spatial resolution < 0.3°). In this experiment, gaze was sampled at 60 Hz; this is a slightly higher sampling rate than in Experiment 1 (50 Hz).

Prior to participation, the following questions were asked of parents: (a) Did your child ever see anybody comb their hair? If yes, how often? (b) Do you comb your child's hair? How often? and (c) Can your child comb his or her own hair? If yes, how often? Following these questions, participants went through the same procedure that is outlined in Experiment 1.

The context video demonstrated the same actor as in Experiment 1 (see Figure 3). In this first video, the model opens a small bag placed on the table, takes out a comb, and places it next to a plate. The model thereafter takes a cup of water and pours the water into the plate. The second movie starts with the model looking into the camera for 1 s with hands on her lap. The model then turns her head and eyes to the plate simultaneously raising her arm to grab the comb. After the comb is picked up the actor dips the front end of the comb in the water while holding the comb by its handle. Following these preparations (similar to the preparations performed in Experiment 1), the model brings the comb to her hair and makes three vertical combing movements after which the comb is brought to the plate again and the same action sequence is repeated three more times. Both spatial and temporal aspects of the stimuli are matched to the stimuli presented in Experiment 1.

Data analysis. All analyses in this experiment were performed using the same analysis tools (with the same criteria) used to analyze the results of Experiment 1. The latencies of participants' goal-directed gaze shifts were related to the movement of the arm and comb toward the model's head. This was done in two separate analyses. In one analysis, the latency of participants' first fixation anywhere on the head was related to the time when the comb first entered the area covering the head (head AOI, see Figure 3a). In the second analysis, the latency of participants' first fixation on the part of the hair that was combed was related to the time when the comb first entered this area (hair AOI; see Figure 3b).

Results

Six-month-old infants attended to the combing action in 38% (*SE* = 5) of all trials. Mean amount of anticipation for these trials equaled 24% (*SE* = 6). Ten-month-old infants and adults attended to 45% (*SE* = 7) and 96% (*SE* = .8) of trials, respectively. Amount of anticipation for these trials equaled 36% (*SE* = 6) for 10-month-olds and 78% (*SE* = 3) for adults.

We could not observe any effect of presentation order across the trials ($p > .05$), so the data were compiled across order. ANOVA analysis performed on the goal fixation latencies produced to the head AOI demonstrated significant age differences, $F(2, 41) = 6.5$, $p = .005$. Post hoc tests demonstrated that adults fixated the goal faster than both infant groups ($p = .01$). According to single-sample t tests, adults were the only group who produced predictive gaze shifts to the head AOI, $t(7) = 3.7$, $p = .008$.

Similar analyses performed on the gaze shifts produced to the hair AOI revealed the same pattern. Again ANOVA analysis demonstrated

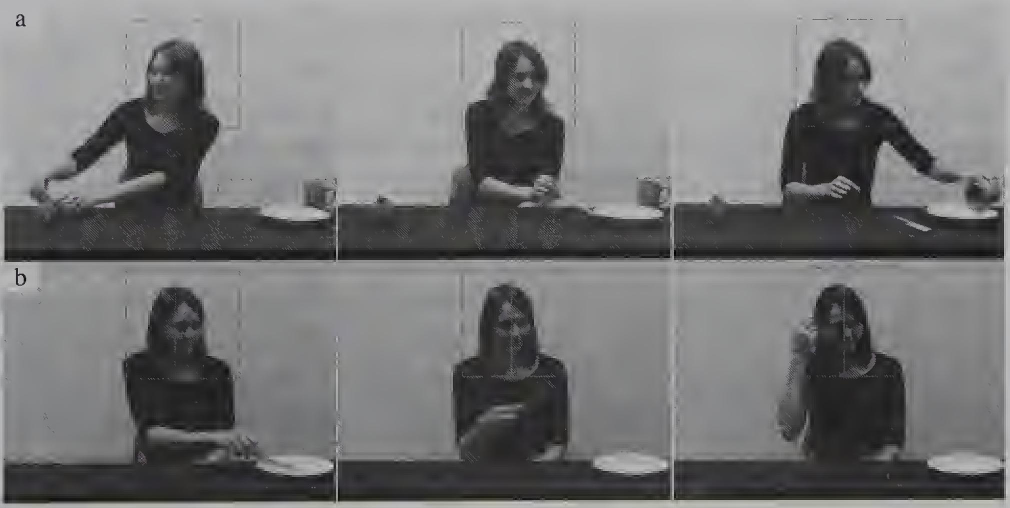

Figure 3. Snapshots from context movie (a) and the combing action (b).
Note. The upper rectangles (dotted line) represent placement of head area of interest (AOI). Narrow upper rectangle (solid line at b) demonstrates placement of hair AOI. The lower rectangle (dotted line) depicts the location of the plate AOI.

significant age differences, *F*(2, 41) = 18, *p* = .001 (see Figure 4); post hoc tests revealed much faster gaze fixations demonstrated by adults (*p* = .001). Moreover, adults were again the only group who produced predictive gaze shifts to the goal area, hair AOI, *t*(7) = 2.7, *p* = .03.

Discussion

Experiment 2 presented participants with a normal, goal-directed, and functional action that maintained the spatial and temporal properties of the feeding action presented in Experiment 1. Despite this, only adults were able to anticipate the goal of this action. This late onset of anticipatory gaze shifts in Experiment 2 does not support the degree of motion hypothesis. The observed action includes a large degree of motion from the arm and comb (matched to Experiment 1); however, this information is not sufficient to allow infants to anticipate the current action goal. Nor does it support the saliency hypothesis, according to which infants might produce an early onset of anticipatory gaze shifts when observing actions directed toward a human head and a delayed onset when observing action directed toward less salient stimuli. In this respect, it should be emphasized that the current finding does not falsify the general assumption that goal saliency is an important aspect of action understanding and goal anticipation. It does, however, suggest that differences in goal saliency cannot account for the large variation in onset of anticipatory gaze shifts observed during observation of feeding (Experiment 1), containment actions (Falck-Ytter et al., 2006), and combing (Experiment 2).

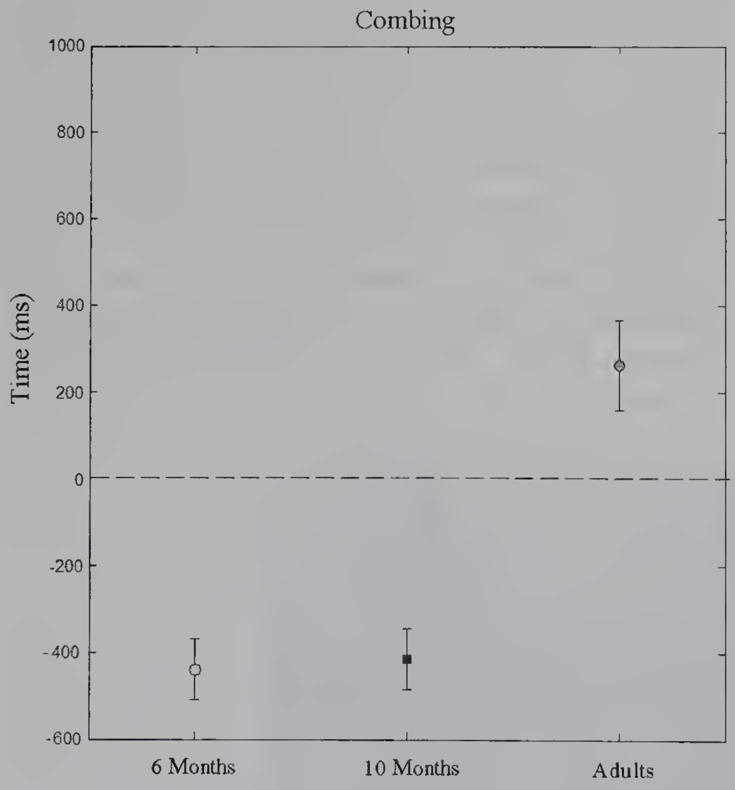

Figure 4. Gaze performance during observation of combing action.
Note. Vertical axis depicts timing of gaze arrival at the hair area of interest (AOI) relative to the time when the comb first entered the Hair AOI. The time when the comb first came into the hair AOI is represented by the horizontal line at 0 ms. Positive values correspond to early arrival of gaze at the target area. Error bars represent standard errors of the mean.

The two different analyses used in Experiment 2 serve somewhat different purposes. By comparing latencies of goal fixations with respect to the part of the hair that was actually combed, we were able to make direct comparisons to Experiment 1. In both experiments, these AOIs cover only the essential goal area (where the spoon and comb interact with the human goal) while maintaining an identical AOI size over the two experiments. It is, however, possible to question the appropriateness of this matched AOI for analyzing the data of Experiment 2. First, infants might find it difficult to anticipate exactly which area of the head the model intends to comb. As such, this analysis might miss a number of anticipations directed toward other parts of the hair. In a similar manner, some infants might believe that this action was directed toward the mouth or some other part of the head, simply because they may have misunderstood the purpose of the action. To control for this possibility, we also reported the latency of gaze shifts to the entire head. As can be seen in Experiment 2, this possibility did not systematically influence the results because infants made few anticipatory gaze shifts in this condition.

General Discussion

This is the first study to demonstrate goal anticipation by 6-month-old infants during observation of manual actions. In addition, 6-, 10-month-olds, and adults all demonstrate faster gaze shifts to the goal of manual actions than during observation of matched SP events. At the same time, both 6- and 10-month-olds fail to anticipate a highly similar combing action with which they have no (or at least limited) experience. Adults, who have much experience with similar events, anticipated the goal of the later action. All of these findings support the experience account, suggesting that our own experience plays an important role when we perceive and anticipate the goal of other people's actions.

The tight connection between the onset of anticipatory gaze shifts and experience performing the same manual tasks in infants suggests that observational experience is not sufficient to guide anticipatory gaze shifts. Instead, it seems that infants rely on a direct matching process that simulates action goals by relating observed events to corresponding manual action plans (Falck-Ytter et al., 2006; Flanagan & Johansson, 2003). Neither of these findings supports the assumption that anticipatory gaze shifts are guided by well-formedness criteria, as defined within the teleological stance framework (Gergely & Csibra, 2003).

Contrary to prior findings, both 10-month-olds and adults anticipated the goal of SP feeding actions (however, with longer latencies than during observation of manual actions). Previous studies have only demonstrated anticipatory gaze shifts to functional goal-directed manual actions, not to SP events (Falck-Ytter et al., 2006; Flanagan & Johansson, 2003) or to nonfunctional arm movements (Gredebäck et al., 2009). These findings suggest that the link between manual feeding actions and anticipation during observation of feeding is less dependent on actually perceiving the manual action. As such, it could be argued that the goal anticipation during observation of feeding is more flexible, or less dependent on, visual information about the hand and arm than what has been demonstrated for other manual actions (Falck-Ytter et al., 2006; Flanagan & Johansson, 2003; Gredebäck et al., 2009).

Of course, it could be claimed that 10-month-olds and adults apply teleological reasoning to anticipate SP-feeding events. However, this suggestion would not be sufficient to explain the faster goal fixation latencies observed during manual feeding actions. Moreover, it would not be able to account for the synchrony in onset between the ability to anticipate the goal of others' actions (Falck-Ytter et al., 2006) and infants' own manual abilities (such as placing objects inside their mouth; Experiment 1). At the same time, it is important to emphasize that there is no empirical evidence (or theoretical claims) that would support the notion that well-formedness criteria (and teleological reasoning) should be especially directed toward anticipating *feeding* actions. Such task specificity is not consistent with the broad applicability and flexibility of teleological reasoning as described by Csibra and Gergely (2007).

Instead, we suggest two alternative, and possibly complementary, explanations for our findings. First, feeding is a biologically rooted action that might hold special meaning to both humans and other species. In other words, understanding of feeding might be phylogenetic primed, enhancing an observer's ability to anticipate feeding actions even when the entire manual action is not clearly observable (SP condition of Experiment 1). Indeed, from an evolutionary point of view it would be of the highest priority to understand the intentions of others in situations that are directly connected to one's own physical survival, such as feeding. It is frequently reported that primates in the wild pay attention to what others are eating (Perry & Manson, 2003) and where they are feeding (Kazahari & Agetsuma, 2008). For example, mantled howler monkeys must carefully watch what their mothers eat in order not to be poisoned (Perry & Manson, 2003). Observation of others is also important when usual food depletes. This has been demonstrated at several Japanese macaque sites where adult males' discovery of new food leads to transmission of the habit to other macaques' (Perry & Manson, 2003). Based on these findings, we assume that humans might be able to extend the range of feeding events that can be mapped on to our own motor capabilities, through processes deeply rooted in our phylogenetic history. The possible evolutionary advantage associated with such an enriched action understanding of feeding is easily perceived: It would allow better access to food and a competitive edge that might enhance chances of survival when resources are scarce.

A second reason might be infants' high frequency of experience being fed. Infants are exposed to feeding, place objects inside their mouths, and develop their own hand–mouth coordination from a very early age. The high frequency of such experience at an early age might make it easier for infants to connect observed events (manual actions and moving spoons) with their own enactment of the goal (opening the mouth to consume the food) and their own experience with putting things into the mouth. All of these experiences might promote an understanding of feeding that exceeds even adults' understanding of other manual actions. Future studies are necessary to investigate how each of previously named factors influences our understanding of others' actions and especially our ability to anticipate the goal of manual feeding actions.

At the same time, if we reason more broadly, it is clear that adults are able to use more than one proactive strategy, when interacting with the world. The use of experience-only strategy would exclude the possibility of making correct predictions in completely new situations. However, taking into account the results of this study, it seems that during development, relying on one's own experience is a leading strategy for perceiving and anticipating the goal of other people's actions.

Relations Between Physiological and Cognitive Regulatory Systems: Infant Sleep Regulation and Subsequent Executive Functioning

Annie Bernier

Stéphanie Bordeleau and Julie Carrier
University of Montreal

The aim of this report was to investigate the prospective links between infant sleep regulation and subsequent executive functioning (EF). The authors assessed sleep regulation through a parent sleep diary when children were 12 and 18 months old ($N = 60$). Child EF was assessed at 18 and 26 months of age. Higher proportions of total sleep occurring at night time, at both 12 and 18 months, were related to better performance on executive tasks, especially those involving a strong impulse control component. Most relations held above family socioeconomic status, prior mental development and concurrent verbal ability. These findings add to previous results with school-age children in suggesting that sleep favors the development of higher order cognitive functions requiring prefrontal cortex involvement.

A crucial developmental task in early childhood is the development of executive functioning (EF). EF refers to higher order cognitive processes, including impulse control, set shifting, and working memory, which aid in the monitoring and control of thought and action (Garon, Bryson, & Smith, 2008; Zelazo, Carter, Reznick, & Frye, 1997). The first signs of EF emerge in infancy as behaviors move from being monitored externally by caregivers to being regulated internally by the child. Individual differences in EF have often been linked to children's theory-of-mind understanding (for a review, see Zelazo, Carlson, & Kesek, 2008) as well as emotional and social competence, moral conduct, and school readiness and achievement (e.g., Blair & Razza, 2007; Carlson & Wang, 2007; Espy et al., 2004; Kochanska, Murray, & Harlan, 2000; van der Sluis, de Jong, & van der Leij, 2007). In contrast to this compelling set of findings, very little is known about the mechanisms that underlie the development of EF. Owing to the central role of frontal brain structures in EF (see Zelazo et al., 2008), and the close connections between early sleep regulation and brain development (Jones, 2005), this report examines the prospective relations between sleep regulation in infancy and subsequent EF.

Sleep is sometimes considered to be the single most important activity of the brain during early childhood (Dahl, 1996). In fact, infants spend over half of their first 2 years of life sleeping, with an average daily sleep duration of about 16–17 hr a day during the 1st month, gradually declining to 14–15 hr at approximately 6 months, and to 13 hr at 2 years of age (Coons & Guilleminault, 1992; Davis, Parker, & Montgomery, 2004; Iglowstein, Jenni, Molinari, & Largo, 2003). Hence, by 2 years of age, the average child has spent nearly 14 months asleep and only 10 months in waking activities (Dahl, 1996). During the same period, the brain undergoes a growth spurt, reaching 90% of its adult size, while myelination and synaptic pruning dramatically alter the landscape of neural networks (Nelson, Thomas, & de Haan, 2006). As

highlighted by Dahl (1996), the fact that evolution has favored the brain to spend considerably more time in a state of sleep than in all waking activities combined at such a time of rapid neural development suggests that sleep may serve a crucial function in brain development.

Consistent with this proposal, numerous studies have demonstrated that different indicators of sleep are associated with infants' and children's cognitive functioning (e.g., Becker & Thoman, 1981; Buckhalt, El-Sheikh, & Keller, 2007; Dearing, McCartney, Marshall, & Warner, 2001; Gomez, Bootzin, & Nadel, 2006; Scher, 2005; Steenari et al., 2003; Touchette et al., 2007). Notably, research has often found EF deficits among children suffering from sleep-disordered breathing (e.g., obstructive sleep apnea; see Beebe, 2006). These executive deficits are considered to be attributable to disrupted sleep, to hypoxemia, or to both (Beebe & Gozal, 2002). These findings with clinical populations appear to extend to the general population as well. Hence, although sleep deprivation in adults has a negative impact on performance on many psychomotor, attentional, and cognitive tasks (Boonstra, Stins, Daffertshofer, & Beek, 2007), it has often been observed that executive tasks are particularly affected by sleep deprivation (for reviews, see Dahl, 1996; Harrison & Horne, 1998; Jones & Harrison, 2001). Such findings have been interpreted as evidence for the notion that the prefrontal cortex, largely implicated in executive functions, may be particularly sensitive to the homeostatic processes underlying sleep regulation (e.g., Horne, 1993; Jones & Harrison, 2001).

Electrophysiological studies provide support for this interpretation by suggesting that sleep may have a localized homeostatic function of particular importance for frontal brain areas. The homeostatic process is a regulating mechanism whereby sleep pressure accumulates with time awake and dissipates during a sleep episode. In humans, the intensity and dynamics of slow-wave sleep (SWS) and slow-wave activity (SWA; spectral power between 0.5 and 4.0 Hz during non-rapid-eye-movement sleep) reflect the time course of the homeostatic process: More time awake produces higher levels of SWS and SWA, whereas more time asleep is associated with lower levels (Achermann, Dijk, Brunner, & Borbély, 1993). Of particular interest for our purposes are studies showing brain regional differences in this process. SWA is more prominent in frontal-central brain areas compared to posterior regions (Werth, Achermann, & Borbély, 1996), and the increase in SWS and SWA after sleep deprivation is larger in frontal than occipital regions (Cajochen, Foy, & Dijk, 1999). In addition, the impact of sleep deprivation on waking electroencephalogram is more prominent in frontal than posterior brain areas (Cajochen, Knoblauch, Krauchi, Renz, & Wirz-Justice, 2001). Thus, as argued by many (Beebe & Gozal, 2002; Dahl, 1996; Horne, 1993), frontal brain regions seem to have a higher need for recovery during sleep than more posterior areas.

Although little research has been conducted with nonclinical samples of children thus far, emerging evidence has begun to suggest there may be a specific link between EF and sleep in childhood. Sadeh, Gruber, and Raviv (2002) found that sleep fragmentation was negatively related to school-age children's performance on tasks requiring executive control, but not to simpler tasks of memory or reaction time. In a subsequent experimental study, Sadeh, Gruber, and Raviv (2003) found that three consecutive nights of at least 30 min of augmented sleep improved school-age children's performance on certain neurobehavioral tasks, including a "continuous performance task" used to assess attention and inhibition in preschoolers (Carlson, 2005). In another experimental study, Randazzo, Muehlbach, Schweitzer, and Walsh (1998) gave 8 preadolescents (10–14 years) one night of sleep restriction (5 hr in bed), and 8 others one night of sleep augmentation (11 hr in bed). They found that while none of the measures involving a low cognitive load (e.g., semantic memory) distinguished the two groups, children in the sleep augmentation group outperformed their sleep-restricted counterparts on the Wisconsin Card Sorting Test, often used as a measure of EF (Zelazo, Müller, Frye, & Marcovitch, 2003).

Hence, there is emerging evidence that sleep may play a specific role in EF in children. Thus far, however, these effects have been observed in children only 7 years and older. Given that major advances in EF take place between 1 and 6 years of age (Zelazo et al., 2008), and that neural density of the frontal lobes begins to decline at about 7 years of age (Huttenlocher, 2002), it appears that the potential impact of sleep on frontal/executive functions may be especially potent earlier in development, when the brain shows substantial dynamic plasticity in accord with experience (Singer, 1995). It is also noteworthy that all studies assessing child sleep and EF have done so concurrently, leaving the possibility open that the links are because of child sleepiness interfering with immediate performance on the more complex tasks. Longitudinal studies are important in teasing apart transient fatigue from persistent effects of sleep difficulties on

EF, which could be attributable to a direct impact of sleep on frontal brain development itself.

Finally, existing studies have used large cognitive batteries and numerous sleep indicators and found links between certain sleep parameters and some, but not all, expected cognitive indices. As highlighted by Buckhalt et al. (2007), drawing valid conclusions on presumed specific links between sleep and EF is complicated by the great variety of cognitive tasks used in different studies, and better construct specificity and measurement are needed. We further argue that appropriate measurement of EF with children should entail a developmental approach. Existing studies of sleep and EF have generally used measures designed to assess executive deficits in brain-injured adult patients. The developmental course and significance of such measures are unclear. In the last few years, developmental researchers have established age-appropriate measures of EF with identified developmental trends (e.g., Carlson, 2005; Hughes & Ensor, 2005; Zelazo et al., 2003), which are likely to be especially useful in drawing developmentally valid conclusions on the impact of sleep on EF in children.

In contrast, there is currently no consensus on the best indicators of sleep quality in infancy and childhood (Hayes, 2002; Jenni & Carskadon, 2007). In fact, a striking aspect of the sleep research involving infants and children is how different sleep parameters are associated with positive outcomes in different studies, and how the same sleep parameters show different (e.g., Anders, Keener, & Kraemer, 1985; Gertner et al., 2002) and sometimes opposite relations (e.g., Borghese, Minard, & Thoman, 1995) to the same outcomes at different ages. In line with Sadeh's (2003) suggestion that a developmental perspective is needed when assessing sleep problems in children, we argue that these age differences are a key aspect of the inconsistency in findings and that developmental considerations should guide the choice of sleep parameters likely to represent meaningful individual differences.

A first consideration is that while greater sleep duration is generally regarded as a positive parameter, a primary regulation task in infancy is to spend gradually *less* time asleep. As reviewed earlier, newborns spend about two thirds of each circadian period asleep, and sleep duration decreases gradually. Acebo et al. (2005) found this decline to be very clear during the 2nd year of life: They observed a significant decrease in total sleep duration reported by parents through a sleep diary between 1 and 2 years of age, followed by stabilization after 2 years. Greater sleep duration may thus be a developmentally inadequate index of sleep quality among infants, and in fact, total sleep duration (recorded by actigraphy) has been shown to be unrelated to cognitive performance in infants (Scher, 2005) and older children (Buckhalt et al., 2007; Sadeh et al., 2002). Another key developmental task in infancy is to adapt to the day–night alternation. Hence, while newborns sleep roughly equal amounts of time in daytime and at night, a circadian rhythm is established over the course of the 1st year, such that infants gradually get most of their sleep at night (Anders & Keener, 1985; Halpern, MacLean, & Baumeister, 1995), although important individual differences exist in the rate of adaptation to the day–night cycle (e.g., St. James-Roberts & Plewis, 1996). This adaptation mostly manifests itself through a decrease in daytime sleep. For instance, Acebo et al. (2005) found significant decreases in parent-reported number of daily naps and number of nap sleep minutes between 12 and 18 and between 18 and 24 months, which accounted for the overall decline in total sleep reported earlier. Hence, a greater proportion of total sleep occurring at night can be considered to be a marker of advanced biobehavioral organization. A third aspect of biological maturation in infancy is the consolidation of sleep patterns into longer uninterrupted bouts of sleep (Anders & Keener, 1985; Coons & Guilleminault, 1984), which also shows substantial interindividual variability (Sadeh & Anders, 1993). In fact, although the developmental milestone of "sleeping through the night" is most often achieved during the 1st year of life, as many as 20%–30% of infants continue to experience fragmented sleep past their 1st year (see Sadeh, 1996). Sleep fragmentation at night has been found to relate negatively to cognitive performance in infants (Scher, 2005) and children (Buckhalt et al., 2007; Sadeh et al., 2002).

This study set out to examine the prospective links between infant sleep regulation and subsequent EF in typically developing children, using a developmental approach to the assessment of both sleep and EF. The sleep parameters retained for their developmental relevance were: (a) the proportion of night time sleep to total sleep and (b) sleep fragmentation. Total sleep duration was also considered, given its frequent use as a sleep index. We used Carlson's (2005) empirically derived guidelines for the measurement of EF with toddlers. It was expected that a higher percentage of night time sleep and fewer nights awakenings at 12 and 18 months would relate to better EF at 18 and 26 months, but not to measures of overall cognitive functioning. In a comprehensive review of the literature on different components of EF among children suffering from sleep-disordered breathing, Beebe (2006) outlines that deficits are particularly consistent in the spheres of sustained attention, vigilance, and impulse control, whereas links with other executive functions, such as working memory or mental flexibility, are very limited. Sadeh et al. (2002) also reported specific links between school-age children's sleep fragmentation and impairments in impulse control. We thus expected that links between sleep and EF would be more marked in the sphere of impulse control.

Method

Participants

Sixty mother–infant dyads (36 girls and 24 boys) living in a large Canadian metropolitan area participated in this study. Families were recruited from birth lists provided by the Ministry of Health and Social Services. Criteria for participation were full-term pregnancy and the absence of any known physical or mental disability in the infant. Family income varied from < $20,000 CDN to over $100,000 CDN, with an average of $70,000 CDN. Mothers were between 24 and 45 years old ($M = 31.7$). Most (68.3%) had a college degree and 86.7% were Caucasian. All but 5 were married or living with the child's father throughout data collection.

Procedure

The dyads took part in three assessments, when children were 12–13 (T1; $M = 12.9$, $SD = 1.2$), 18 (T2; $M = 18.3$, $SD = 1.1$), and 26 months of age (T3; $M = 26.3$, $SD = 0.8$). Children's sleep regulation was assessed with a sleep diary completed by mothers at T1 and T2, whereas EF was assessed at T2 and T3 (see the following). Child overall cognitive functioning was assessed at all three time points (i.e., mental development at T1 and expressive vocabulary at T2 and T3).

Measures

Sleep Regulation

The parent sleep diary is a noninvasive measure widely used in sleep research with infants and children (e.g., Acebo et al., 2005; Corkum, Panton, Ironside, MacPherson, & Williams, 2008; Sadeh, 1994, 1996; Werner, Molinari, Guyer, & Jenni, 2008). The diary records, on a timeline of 24 hr for several consecutive days, the sleep pattern of the child as it unfolds. The parent is asked to indicate, for each half-hour, whether the child was awake or asleep, thus representing all periods of sleep and wake, including diurnal naps and nocturnal wakes. The parent is also requested to report any unusual event that might have disturbed the child's sleep pattern, such as illness or traveling. Although more days of assessment provide more data and thus can conceivably reduce measurement error, parent compliance in filling out the diary becomes an increasingly greater concern with lengthier periods of diary assessment (Sadeh, 2008). St. James-Roberts and Plewis (1996) found that 3 days represented the optimal duration to obtain reliable data while accounting for mothers' compliance in filling out diaries of infant fussing, feeding, and sleeping patterns. Consequently, mothers in this study were asked to complete the diary on 3 consecutive days during which their child had a fairly usual routine, at both 12 and 18 months of age. Three parameters were derived from the sleep diary: total sleep duration, percentage of total sleep occurring at night time (between 7 p.m. and 7 a.m.), and sleep fragmentation, that is, number of night awakenings. To account for different sleep schedules among children, wake periods occurring toward the beginning or the end of the predefined night period were considered night awakenings only if they were preceded and followed by at least 30 min of consecutive sleep.

Owing to some families' failure to return sleep diaries, or to diaries considered unusable (generally because they were completed on days marked by unusual events, such as sleeping at friends' homes or an illness in the child), 9 of the 60 families did not have valid sleep data at 18 months. Analyses pertaining to 18-month sleep are thus conducted with 51 children, whose mean age, other demographic information, and EF did not differ from the total sample.

Child EF: 18-Month Assessment

Until recently, the earliest measurement guidelines for EF started at 24 months (Carlson, 2005). However, based on neuropsychological testing, which suggests that certain aspects of EF begin to develop earlier, notably working memory, our team developed a downward adaptation of a working memory task originally designed for 2-year-old children.

Hide the Pots (adapted from Hughes & Ensor, 2005; see also Uzgiris & Hunt, 1975—Scale I, Search for Hidden

Objects). An attractive sticker was hidden in full sight of the child under one of three opaque pots of different colors. In the warm-up phase, no further action took place, and the child was immediately asked to retrieve the sticker where it was hidden. Three practice trials were conducted (one with each pot). This phase was intended to introduce children to what was expected. In the second phase, the experimenter also hid the sticker once under each pot but covered the pots with a blanket on each trial before immediately inviting the child to find the sticker. The child thus had to hold the location of the sticker in memory, remove the blanket, and reach for the pot where the sticker was hidden. Scores consisted of the number of trials (0–3) where the child found the sticker on his or her first attempt. In a prior study, this working memory task was shown to be predictive of later EF performance on well-validated tasks (Bernier, Carlson, & Whipple, 2010).

Child EF: 26-Month Assessment

The tasks conducted at 26 months were chosen based on Carlson's (2005) measurement guidelines with the aim of maximizing detection of individual differences in three dimensions of EF: working memory, inhibitory control, and set shifting.

Spin the Pots (Hughes & Ensor, 2005). Children were asked to search for stickers that were hidden in opaque pots, subsequently covered and rotated 180°. Six stickers were hidden in eight pots of very different visual appearances, thus leaving two pots empty. Each time a sticker was found, it was given to the child and all eight pots were covered and rotated 180° again. Therefore, as children found stickers, there was an increasingly large number of empty pots on the tray. The score was calculated as 16 (which is the maximum number of trials allowed) minus the number of errors made (i.e., looking under a pot in which no sticker had been hidden, or perseverative looking).

Delay of Gratification (Kochanska et al., 2000). The experimenter placed a present under a transparent cup and asked children to wait until she rang a bell before retrieving it. Four trials were conducted, where the child had to wait 5, 10, 15, and then 20 s. Scores were the number of seconds waited on each trial, that is, the time elapsed between the experimenter placing the cup and the child touching it (if he or she did so before maximum waiting time had elapsed).

Shape Stroop (Kochanska et al., 2000). Children were first shown six cards depicting three small and three large fruits, and were asked to point to each in turn to ensure that they knew the names and sizes of the fruits (e.g., ''Show me the big apple''). They were then shown three cards, each depicting one of the small fruits embedded in one of the larger (mismatching) ones, and asked to point to each of the small fruits in turn (e.g., ''Show me the *little* banana''). The score consisted of the number (0–3) of small fruits correctly pointed to.

Baby Stroop (adapted from Hughes & Ensor, 2005). Children learned a rule for feeding two dolls, feeding the ''mommy'' doll with a larger spoon and the baby doll with a smaller spoon. As soon as the child clearly understood the rule, it was reversed such that the child was asked to feed the larger doll with the smaller spoon once, and then to feed the baby doll with the larger spoon on the next trial. Children got 1 point for feeding each doll with the correct spoon on their first attempt. Scores thus ranged from 0 to 2.

At both T2 and T3, administration of the EF tasks was videotaped for later coding. Because we were interested in individual differences rather than group patterns, EF tasks were administered in fixed order.

General Cognitive Ability

At 12 months, children's general cognitive functioning was assessed with the Mental Development Index of the Bayley Scales of Infant Development (MDI; Bayley, 1993), a standardized test of cognitive development for children aged 1–42 months. A total of 23 protocols (38%) were double-coded by independent raters (using the video recording of the administration). Intraclass correlation (ICC) between raters' MDI scores suggested good reliability, ICC = .85.

At both 18 and 26 months, we assessed child expressive vocabulary, often used as a proxy for overall cognitive ability, with the MacArthur Communicative Development Inventory (MCDI; Fenson et al., 1994). Parents were asked to identify from a list which words they had heard their child say. Fenson et al. report excellent reliability indices for the instrument.

Results

Preliminary Analyses

Sleep Parameters

Stability of sleep parameters across the 3 days was moderate to high, with average between-day correlations of $r = .61$, $p < .001$, for total sleep duration; $r = .64$, $p < .001$, for percent of night time sleep; $r = .69$, $p < .001$, for number of night awakenings at 12 months; $r = .60$, $p < .001$, for total sleep duration; $r = .63$, $p < .001$, for percent of night sleep; and $r = .78$, $p < .001$, for number of night awakenings at 18 months. To increase reliability of estimates, data were thus averaged across the 3 days for each sleep parameter. Correlations were lower when looking at continuity between 12 and 18 months: $r = .44$, $p < .01$, for total sleep duration; $r = .46$, $p < .01$, for percent of night sleep; and $r = .52$, $p < .01$, for number of night awakenings. Given these correlations and the data presented earlier suggesting the importance of an age-sensitive approach to the assessment of sleep among infants, the 12- and 18-month parameters were thus kept as distinct variables in the remainder of the analyses. Table 1 presents descriptive statistics for all sleep and EF variables. The six sleep variables showed satisfactory variability, although night awakenings were fairly infrequently reported. EF tasks also showed adequate variability, although Baby Stroop was positively skewed, whereas the 5- and 10-s Delay of Gratification trials were negatively skewed.

Table 1
Mean, Standard Deviation, and Range for All Sleep and Executive Functioning (EF) Measures

Variable	*M*	*SD*	Observed range	Theoretical range
Sleep 12 months				
Total sleep duration (hours)	13.06	1.39	9.75–16.50	0–24
% of night sleep	78.20	5.80	61–91	0–100
Number of night awakenings	0.98	1.38	0–7	0–N/A
Sleep 18 months				
Total sleep duration (hours)	13.09	1.06	10.10–15.25	0–24
% of night sleep	79.40	6.40	57–91	0–100
Number of night awakenings	0.58	1.20	0–5	0–N/A
Child EF 18 months				
Hide the Pots	1.33	0.93	0–3	0–3
Child EF 26 months				
5-s delay	4.81	0.71	1–5	0–5
10-s delay	9.34	1.84	1–10	0–10
15-s delay	12.79	4.51	0–15	0–15
20-s delay	14.91	7.48	0–20	0–20
Spin the Pots	10.39	3.45	4–16	0–16
Shape Stroop	1.58	1.20	0–3	0–3
Baby Stroop	0.43	0.74	0–2	0–2

Note. Values for all sleep variables are averages of the 3 days of data.

Executive Function Data Reduction

The 26-month EF scores of all 60 children, including those for whom sleep data were not available at T2, were submitted to a principal component analysis (PCA) to reduce the number of data points and compute more reliable aggregate estimates. The PCA yielded a two-factor solution (eigenvalues > 1.0) representing 68.8% of the total variance. These two factors were submitted to a principal axis rotation (oblimin). Factor loadings for 15-s delay (.82), 10-s delay (.80), 5-s delay (.78), and 20-s delay (.56) suggest that the first factor taps impulse control, whereas the second factor appears to represent working memory, set shifting, and inhibitory control: Spin the Pots (.78), Baby Stroop (.58), and Shape Stroop (.37). No cross-loadings (above .25) were observed. Studies of EF in young children have found similar factor structures, in which tasks involving delay of gratification load on one factor, whereas tasks entailing different degrees of working memory, set shifting, and inhibitory control load on a separate factor (Carlson, Mandell, & Williams, 2004; Carlson & Moses, 2001; Davis-Unger & Carlson, 2008). The authors have labeled these two factors Delay (referred to here as Impulse Control, to highlight the skill required rather than the task) and Conflict-EF, respectively. Given that the current factor structure was very clear empirically and reproduced these two dimensions, two averaged standardized scores were computed and used in further analyses. Impulse Control and Conflict-EF were moderately correlated, $r = .33$, $p < .05$. The 18-month EF assessment consisted of the single task presented earlier and assessing working memory. This 18-month working memory score was correlated with 26-month Conflict-EF, $r = .32$, $p < .05$, and 26-month Impulse Control, $r = .27$, $p < .05$.

Sociodemographic Variables

We next examined whether sociodemographic variables (child age and gender, number of siblings, maternal and paternal age and education, and family income) were related to sleep or EF variables. Results showed that children of more educated mothers, $r = .23$, $p < .05$, and fathers, $r = .25$, $p < .05$, performed better on working memory at 18 months, and children of more educated mothers performed better on Conflict-EF at 26 months, $r = .23$, $p < .05$. Furthermore, children whose parents earned higher incomes had greater percentages of night sleep at 12 months, $r = .32$, $p < .01$, and performed better on Conflict-EF at 26 months, $r = .30$, $p < .05$. In contrast, no relations with EF or sleep were found for child gender, age, or number of siblings. Given the high correlations (ranging from .55 to .66) between maternal and paternal education and family income, these three variables were standardized and averaged into a composite index of socioeconomic status (SES), which is covaried in the main analyses.

General Cognitive Ability

Next, we examined whether child overall cognitive functioning was related to EF performance. As is often reported in previous studies (e.g., Carlson et al., 2004; Hughes & Ensor, 2005), prior mental development (12 months) was related to all three EF indices (*r*s varying between .22 and .27, *p*s < .05). Concurrent (18 or 26 months) expressive verbal ability was also associated with EF performance, with correlations varying between .30 and .34, *p*s < .05.

Last, correlations were run between indicators of overall cognitive functioning (mental development and verbal ability) and sleep parameters at 12 and 18 months. Only one correlation reached significance: A greater percentage of night time sleep at 12 months was related to a larger expressive vocabulary at 26 months, $r = .29$, $p < .05$. All other correlations were nonsignificant and below .17. Note that this pattern of relations was very similar when holding SES constant.

Table 2
Zero-Order Correlations Between Executive Functioning (EF) at 18 and 26 Months and Sleep Duration, Percent of Night Sleep, and Sleep Fragmentation at 12 and 18 Months

	18-month working memory	26-month conflict-EF	26-month impulse control
Sleep duration			
12 months	−.11	−.10	−.06
18 months	−.16	.09	−.16
% of night sleep			
12 months	.06	.27*	.32*
18 months	.35*	.13	.40**
Fragmentation			
12 months	.03	−.03	.04
18 months	.12	−.07	.01

*$p < .05$. **$p < .01$.

Main Analyses

To address our primary aim, we next examined whether sleep parameters were associated with concurrent and subsequent child performance on EF tasks. As displayed in Table 2, sleep duration and sleep fragmentation did not relate to any EF score, all *r*s < .16, *ns*. These two sleep indices were therefore dropped from further analyses. In contrast, percentages of night sleep were related to several EF indices. Percent of night sleep at 12 months was correlated with both Conflict-EF and Impulse Control at 26 months. Percent of night sleep at 18 months also correlated with Impulse Control at 26 months, although not with Conflict-EF. However, it was associated with concurrent working memory. In all cases, relations were positive; that is, children getting a greater proportion of their sleep at night performed better on concurrent or later EF tasks.

Thus, percent of night sleep at both ages considered was related to EF although not to general cognitive ability. To submit this to an especially stringent test focusing on what is unique to EF above overall cognitive functioning, each EF index was submitted to a hierarchical regression analysis involving three steps: SES was entered in a first block, followed by indicators of general cognitive performance in a second block, and by relevant sleep parameters in a third block. Owing to the correlations presented in Table 2, the third block consisted of the 18-month percent of night sleep when predicting 18-month working memory, and the 12-month percent of night sleep when predicting 26-month Conflict-EF. Both 12- and 18-month percents of night sleep were found to be uniquely related to 26-month Impulse Control (see Table 2), but their intercorrelation ($r = .46$, $p < .01$) argued against entering them in the same equation (predictors moderately to highly interrelated can cause unreliable estimates; Tabachnick & Fidell, 2007). Impulse Control was thus submitted to two distinct regression equations, one with each night sleep percent entered in the third block.

Table 3 (Equations 1–4) shows that SES predicted between 0.1% and 6.7% of the variance in EF performance, whereas overall cognitive performance contributed an additional 5.1%–10.2%, and sleep parameters added between 4.8% (Conflict-EF) and 9.8% (Impulse Control with 18-month night sleep) of explained variance. Specifically, after controlling for SES and cognitive performance, children getting a higher percentage of their sleep during the night at 12 months performed marginally better on

Table 3
Summary of Regression Analyses Predicting Executive Functioning (EF) Performance at 18 and 26 Months

	Criterion			
Model	R^2	ΔR^2	*F* change	β
1. 18-month working memory				
1. SES	.049		2.98†	.21†
2. Mental development				.35*
Verbal ability	.151	.102	3.52*	.11

Verbal ability	.052	.051	1.33	.17
3. 18-month working memory	.098	.046	2.98†	.18†
4. 12-month % night sleep	.151	.053	4.71*	.26*
7. 26-month impulse control				
1. SES	.001		0.39	.01
2. Mental development				.10
Verbal ability	.052	.051	1.33	.17
3. 18-month working memory	.098	.046	2.98†	.18†
4. 18-month % night sleep	.168	.070	4.99*	.30*

Note. SES = socioeconomic status.
$^{\dagger}p < .10$. $^{*}p < .05$.

Conflict-EF, β = .22, $p < .10$, and significantly better on Impulse Control at 26 months, β = .30, $p < .05$. In addition, children getting a higher percentage of their sleep during the night at 18 months performed better on concurrent working memory, β = .29, $p < .05$, and later Impulse Control, β = .33, $p < .05$. Hence, all direct relations uncovered between sleep and EF (Table 2) remained significant after accounting for SES and general cognitive ability, with the exception of the relation between 12-month night sleep percent and 26-month Conflict-EF, which became marginally significant.

Finally, we examined whether sleep was related to later changes in EF performance by analyzing relations between night sleep percents and 26-month EF, partialing out previous (18-month) working memory, in addition to the previous controls. Working memory at 18 months was therefore included in a third block of the three equations predicting 26-month EF, whereas sleep parameters were entered last, in a fourth block of each equation. Results, presented in Table 3 (Equations 5–7), indicated that 26-month Impulse Control was positively associated with night sleep percent at both 12, β = .26, $p < .05$, and 18 months, β = .30, $p < .05$, over and above SES, general cognitive ability, and prior EF performance.

Discussion

The aim of this report was to investigate the prospective links between sleep regulation and EF in normally developing infants and toddlers. Based on prior work with normative and clinical populations of older children, it was expected that more mature sleep, indicated by a higher percentage of total sleep occurring during night time and fewer night awakenings, would relate to better performance on EF tasks but not to general cognitive functioning. With some exceptions, the results provided support for this hypothesis. Whereas only one relation between sleep and general cognitive functioning (i.e., 26-month vocabulary) was found to be significant, the percentage of night time sleep, at both 12 and 18 months of age, was associated with several EF indices. Hence, 12-month night sleep was related to both conflict-EF and impulse control at 26 months of age, whereas 18-month night sleep was related to concurrent working memory and later impulse control. Children getting a higher percentage of their sleep during night time were more advanced in their EF development. Importantly, these relations appear to be robust and specific to EF, as they held after controlling for SES as well as for two well-documented correlates of EF: overall mental development and verbal ability. Finally, the longitudinal links between percentage of night time sleep at 12 and 18 months and 26-month impulse control both remained significant even after controlling for 18-month working memory, SES, Bayley's MDI, and MacArthur verbal ability scores. In contrast, parent-reported night awakenings at either age did not relate to EF performance, nor did total sleep duration.

These findings provide support for the hypothesis that sleep is specifically associated with frontal/executive functions in children. The current results are in line with previous correlational and experimental studies with adults (see Dahl, 1996; Harrison & Horne, 1998; Jones & Harrison, 2001) and children of clinical (see Beebe, 2006) and normative populations (Randazzo et al., 1998; Sadeh et al., 2002, 2003). They also extend previous findings in several important ways. Notably, this is the first study, to our knowledge, to use a longitudinal design and developmentally sensitive measures to investigate prospective links between early sleep and later child EF. Such an approach is especially helpful in disentangling temporary child sleepiness from enduring effects of impaired sleep. In addition, previous studies investigated sleep–EF links in children 7 years and older, that is, after the decline in neural density of the frontal lobes has begun (Huttenlocher, 2002). Finding similar relations between sleep and performance on frontal tasks much earlier in life speaks to the developmental robustness of the associations. We see these results as particularly meaningful given that they are based on naturally occurring variations in sleep patterns, which are much less dramatic than diagnosed sleep disorders or experimental manipulations of sleep duration.

These results raise the possibility that infant sleep affects developing brain structures in the first 2 years of life, thereby setting in motion a cascade of neural effects that may carry substantial implications for later EF. The multiple studies that have demonstrated that sleep plays a crucial role in learning and memory among adults (see Rauchs, Desgranges, Foret, & Eustache, 2005; Walker & Stickgold, 2006) are useful in identifying the mechanisms through which sleep could affect brain development. It is increasingly believed that a number of cellular and biochemical mechanisms during sleep may facilitate brain plasticity. Animal and human studies have shown that neuronal circuits active during previous learning are reactivated during sleep (Peigneux et al., 2004; Rasch & Born, 2007). In addition, proteins associated with brain plasticity and learning are up-regulated during sleep (Basheer, Brown, Ramesh, Begum, & McCarley, 2005; Cirelli, 2005). Studies in kittens have demonstrated a direct impact of sleep and sleep deprivation on experience-dependent brain plasticity (Frank, Issa, & Stryker, 2001; Frank, Jha, & Coleman, 2006; Jha et al., 2005). It has also been proposed that sleep would induce a progressive downscaling of synaptic strength accumulated during the day to reach an energetically suitable level and make efficient use of cerebral gray matter (Tononi & Cirelli, 2006). Finally, Gaillot (2008) cited evidence showing that brain glycogen, a source of stored energy that is used to support brain activity, is depleted during activities that tax executive control systems and restored during sleep. He thus proposed that one function of sleep might be to replenish brain glycogen stores, which in turn accounts for improved executive function performance. These restorative features of sleep may be especially prominent in the frontal cortex, which is one of the most active and most densely connected brain regions during wake time, and may thus require more recuperation during sleep (Cajochen et al., 2001; Dahl, 1996; Horne, 1993). The findings of this study are consistent with the notion of a direct impact of sleep on brain plasticity, and thus brain development, beginning early in life.

In contrast, our results could also suggest that both percentage of night time sleep and performance on EF tasks are indices of maturation of the central nervous system, in the absence of a causal link between the two. The decline in total sleep duration, largely attributable to a decrease in daytime sleep (Acebo et al., 2005; Coons & Guilleminault, 1992; Davis et al., 2004; Iglowstein et al., 2003), and adaptation to the day–night alternation, resulting in increased night sleep and decreased daytime sleep (Anders & Keener, 1985; Halpern et al., 1995; St. James-Roberts & Plewis, 1996) are well-documented changes in the organization of sleep–wake patterns during infancy, which are often presumed to result from neurological maturation. In the same vein, maturation of the frontal lobes is associated with increments in EF performance during early childhood (see Zelazo et al., 2008). Hence, although the links observed here between sleep and EF appear robust, further research is needed to sort out the sequence of events. Adult and animal brain plasticity research suggests that infant sleep could affect the developing brain structures directly through a number of biochemical mechanisms identified earlier, and experimental studies with both children and adults do suggest a causal link between sleep and EF performance (e.g., Jones & Harrison, 2001; Sadeh et al., 2003). However, the current correlational design does not rule out an alternative explanation, according to which brain maturation would be reflected in both the early organization of sleep–wake patterns and later EF, rather than being the mechanism accounting for a causal link between early sleep and later EF. In fact, the two possibilities are not mutually exclusive, and we would argue that dynamic bidirectional effects are likely to be at play, in which initial maturation of brain structures allows for the establishment of an increasingly mature sleep–wake organization, which in turn favors further brain maturation/plasticity and hence, the emergence of executive control capacities.

An alternate account of the findings involves the family context, which research increasingly suggests is closely linked to child sleep (see Dahl & El-Sheikh, 2007; Jenni & O'Connor, 2005). Factors, such as SES (Acebo et al., 2005), family stress (e.g., Bates, Viken, Alexander, Beyers, & Stockton, 2002), parental psychopathology (Seifer, Sameroff, Dickstein, Hayden, & Schiller, 1996), and marital discord (El-Sheikh, Buckhalt, Mize, & Acebo, 2006) have all been shown to be linked to children's sleep. Specific parental behaviors have been shown to relate to child sleep as well, notably parental warmth (Adam, Snell, & Pendry, 2007) and bedtime behaviors (Morrell & Steele, 2003). Importantly, family factors, such as SES (e.g., Mezzacappa, 2004) and parental behaviors (Bernier et al., 2010; Hughes & Ensor, 2009) are increasingly documented correlates of child EF as well. Hence, one may propose that the links found here between child sleep and EF could be owing to a common underlying influence of the family environment: Well-organized families, characterized by clear limit setting, and warm parent–child relations, could constitute a context likely to favor the orderly development of both sleep patterns and EF in the young child. However, the links between child sleep and family functioning appear to be bidirectional, as infant and child sleep difficulties have been found to predict parents' own sleep difficulties, marital discord, negative mood, and increased stress (Meijer & van den Witenboer, 2007; Meltzer & Mindell, 2007). This raises yet another hypothesis: that early sleep is linked to child EF through its intermediate impact on parents' psychological adjustment. Hence, while the current findings add to an emerging literature documenting links between child sleep and EF, longitudinal designs entailing careful examination of family context variables are necessary for the continued investigation of the neural and social mechanisms linking sleep, EF, and family relations.

Overall, the results suggest that the proportion of night time sleep at 12 and 18 months is relevant to the prediction of child EF. Results were different when considering the other sleep parameters. Although the absence of relations between EF and total sleep duration was expected because of the developmentally inappropriate nature of sleep duration as an index of sleep maturation during infancy, we did expect to find relations with night awakenings. The null findings for sleep fragmentation, rather than questioning the importance of long uninterrupted bouts of sleep in early EF development, may reflect methodological imprecision. In contrast to general sleep questionnaires, sleep diary data converge with objective sleep data gathered by actigraphy, including studies of infants and children (Acebo et al., 2005; Sadeh, 1996, 2004; Werner et al., 2008). In fact, a parent sleep diary is proposed to be interchangeable with actigraphy when assessing sleep schedules, for instance, sleep onset and duration (Sadeh, 2008; Werner et al., 2008). However, the diary method yields less individual variation than actigraphy (Sadeh, 1996), particularly with respect to night awakenings, which tend to be underestimated by parents (Sadeh, 2008; Werner et al., 2008). For instance, Sadeh (1996) found a correlation of .60 between night awakenings reported by parents and as assessed by actigraphy among infants 7–26 months old, while correlations for sleep schedule parameters (e.g., sleep duration) were all above .70. This would be because of many infants' capacity to self-soothe and go back to sleep without parental intervention. In line with this, Keener, Zeanah, and Anders (1988) as well as Minde et al. (1993) observed that while a majority of infants did wake up during the night, a substantial proportion could fall back asleep by themselves, and their awakenings thus went unnoticed by their parents. Accordingly, the use of objective sleep assessments, such as actigraphy, appears necessary for a thorough investigation of the links between early EF development and more subtle indices of sleep consolidation, especially night awakenings.

Another limitation of this study is that given the modest sample size, we could not correct statistically for the number of analyses run without compromising statistical power. This may have increased the risk of Type I error, despite the steps that were undertaken to reduce the number of analyses and variables. Future studies should therefore confirm the current findings with larger samples to achieve an optimal balance between Type I and Type II errors.

The longitudinal findings with the impulse control aspect of EF at 26 months were more compelling and more robust statistically than those with conflict-EF. Impulse control was related to the percentage of night time sleep assessed both 8 and 14 months earlier, and these relations held above

SES, general cognitive functioning, and even 18-month EF. These findings pointing to impulse control as particularly sensitive to sleep are in line with the results found in pediatric populations suffering from sleep apnea (for a review, see Beebe, 2006), with Sadeh et al.'s (2002) findings with nonclinical school-age children, and are reminiscent of the sleep difficulties often reported among children suffering from externalizing disorders characterized by poor impulse control (Owens, 2005; Touchette et al., 2007). They also remind us that EF is constituted of a heterogeneous set of skills (see Garon et al., 2008) that may show distinct relations to different aspects of the child's experience. It was recently found that conflict-EF is related to the quality of prior parent–infant interactions, whereas impulse control is not (Bernier et al., in press). One could thus speculate that different experiential pathways lead to the development of specific aspects of EF, with perhaps social and relational factors (e.g., language stimulation and parent scaffolding) playing a greater role in conflict-EF, whereas impulse control may be driven to a greater degree by biological factors, such as sleep, temperament, or neuroendocrine regulation. One should bear in mind, however, that these putative pathways would likely not be independent of one another, as more organized and well-functioning families appear better equipped to foster both infant sleep regulation and the development of EF.

This study suggested that greater proportions of total sleep occurring at night time are related to children's higher EF performance up to 14 months later, especially on tasks involving a strong impulse control component. These findings add to an emerging literature focusing on the developmental antecedents of children's EF, which has begun to identify parenting as a social precursor of child EF (Bernier et al., 2010; Hughes & Ensor, 2009). Given that parenting is proposed to play a role in the consolidation of sleep–wake patterns (Anders, 1994; Goodlin-Jones, Burnham, Gaylor, & Anders, 2001), and that there is some overlap between different aspects of EF, it is likely that biological and environmental factors interact in complex ways in shaping EF, with specific biological and environmental factors carrying different weights in the prediction of different aspects of EF at different ages. Given the compelling research demonstrating that variation within the normative range of EF performance is meaningful for child adjustment in several spheres, an important agenda for future research is to unravel the neural and social pathways that lead to its optimal development.

A model of the relations among cognitive precursors, early numeracy skill, and mathematical outcomes was tested for 182 children from 4.5 to 7.5 years of age. The model integrates research from neuroimaging, clinical populations, and normal development in children and adults. It includes 3 precursor pathways: quantitative, linguistic, and spatial attention. These pathways (a) contributed independently to early numeracy skills during preschool and kindergarten and (b) related differentially to performance on a variety of mathematical outcomes 2 years later. The success of the model in accounting for performance highlights the need to understand the fundamental underlying skills that contribute to diverse forms of mathematical competence.

How do children acquire skill in conventional mathematics? Researchers have used information from a variety of sources to address this question, including longitudinal studies of normally developing children (Aunola, Leskinen, Lerkkanen, & Nurmi, 2004; Bull, Espy, & Wiebe, 2008; DeSmedt, Verschaffel, & Ghesquière, 2009; Durand, Hulme, Larkin, & Snowling, 2005; Jordan, Kaplan, Locuniak, & Ramineni, 2007; Jordan, Kaplan, Oláh, & Locuniak, 2006; Locuniak & Jordan, 2008; Passolunghi, Vercelloni, & Schadee, 2007), research with children who have severe mathematics difficulties (i.e., dyscalculia; Berch & Mazzocco, 2007), and studies of children who have congenital syndromes that affect their mathematical learning (Ansari et al., 2003; Barnes, Smith-Chant, & Landry, 2005; DeSmedt et al., 2007; Mazzocco & McCloskey, 2005). However, only a few models of the relations between early cognitive abilities and mathematics outcomes have emerged (Bisanz, Sherman, Rasmussen, & Ho, 2005; cf. Desoete & Grégoire, 2006; Durand et al., 2005; Krajewski & Schneider, 2009). Furthermore, it is unclear how early numeracy skills (i.e., children's evolving knowledge about number and quantity) are connected to later mathematical performance. To address these gaps, we propose and test a model of mathematical development in which linguistic, quantitative, and spatial attention skills have distinct roles in children's acquisition of mathematics.

Proposed Model: Pathways to Mathematics

Dehaene and colleagues (Dehaene, Molko, Cohen, & Wilson, 2004; Dehaene, Piazza, Pinel, & Cohen, 2005; Spelke & Dehaene, 1999) have proposed that numerical processing involves three separate neural circuits in the parietal lobe. First, linguistic numerical tasks, such as retrieving answers to arithmetic combinations (e.g., 6 × 7), activate a region of the left angular gyrus that has been linked to language processing, including reading and phoneme

---

This research was supported by Standard Operating Grants from the Social Sciences and Humanities Research Council of Canada to J. LeFevre, J. Bisanz, S. Skwarchuk, B. Smith-Chant, and D. Kamawar. We thank the many graduate student colleagues and undergraduate researchers who contributed to this research. Lori Mergulhao in Winnipeg and Nicole Vachon in Peterborough provided invaluable organizational acumen. We thank all of the children who participated for their interest and enthusiasm. We are also grateful to the teachers, principal, parents, and other school board contacts who enabled this research.

detection. The second circuit activates portions of the posterior superior parietal lobule and is involved in spatial attention. The third circuit is activated in quantity tasks, such as magnitude comparison. It implicates the horizontal segment of the intraparietal sulcus (HIPS). Butterworth and colleagues (Butterworth, 1999, 2005; Castelli, Glaser, & Butterworth, 2006; Gelman & Butterworth, 2005) also argue for a brain-based number module in the HIPS that is specialized for processing numerosity or quantity. They propose that impairment of this module may be the source of developmental dyscalculia. Notably, although both Dehaene and Butterworth propose a ''core quantity system,'' Dehaene's model is focused on the processing of approximate magnitudes, whereas Butterworth proposes that the core quantity system is specialized to process small exact quantities. Despite these differences across theories, researchers generally agree that only the circuit associated with processing magnitude represents a distinct numerical component. The other two circuits involved in numerical tasks, the linguistic and spatial attentional circuits, are shared across a variety of cognitive tasks.

This neuropsychological account of numerical processing is consistent with the view that the development of mathematical skills involves several distinct cognitive systems (see also Ansari, 2008; Halberda, Mazzocco, & Feigenson, 2008). Accordingly, we formulated a model of numerical development that has three independent cognitive precursors or *pathways*: linguistic, quantitative, and spatial attention. All three pathways are hypothesized to contribute both to the development of early numeracy skills (i.e., before children have much formal instruction) and to children's acquisition of formal mathematical knowledge in school. Based on the model, we proposed two hypotheses about the course of numerical development in children between the ages of 4 and 8. In this article, we tested the model with longitudinal data.

Assessing the Pathways Model

Hypothesis 1: Linguistic, quantitative, and spatial attention pathways contribute independently to early numeracy

The first hypothesis was that linguistic, quantitative, and spatial attention precursor skills form distinct pathways that are independently related to early numeracy performance (i.e., knowledge that children acquire before formal schooling). This hypothesis leads to four predictions. First, linguistic skills should strongly predict children's performance on early numeracy measures that involve knowledge of the symbolic number system (such as naming numbers or writing Arabic digits) because learning the rules of the number system is assumed to be similar to mastering any symbolic representational system (e.g., written language). Second, quantitative precursors should predict early numeracy skills that require children to represent and operate on quantities (e.g., determining more and less, part–whole comparisons, and nonverbal arithmetic). Third, if the two skill pathways are distinct in the early stages of numeracy acquisition, then linguistic and quantitative early numeracy skills will not be strongly related. Fourth, spatial attention will contribute independently of linguistic and quantitative skills to both kinds of early numeracy performance. This prediction is consistent with Dehaene et al.'s (2005) view that the parietal circuit involved in spatial attention is general and not specifically connected to particular numerical tasks.

Children's early numeracy skills, measured before or during kindergarten, predict performance on conventional mathematics tests in the first few years of formal schooling (e.g., Aunola et al., 2004; Bull et al., 2008; Jordan et al., 2006; Jordan et al., 2007; Passolunghi et al., 2007). However, researchers have not identified a consistent and coherent set of cognitive skills that are predictive of early numeracy development. The Pathways model provides a framework to organize potential precursors. Aunio et al. (2006) reported support for distinct linguistic and quantitative pathways for Chinese and Finnish children, ranging in age from 4.5 to 7.5 years. Chinese children outperformed the Finnish children on the linguistic tasks (e.g., producing the number word sequence to 20) at both younger and older ages, but on the quantitative tasks (e.g., determining which set of objects had more) Chinese children outperformed the Finnish children only at the older ages. Similarly, Jordan et al. (2006) obtained a two-factor solution in an analysis of their early numeracy battery: Tasks requiring linguistic number knowledge (story problems and verbally presented number combinations) were distinguished from all other measures, most of which required quantitative knowledge but little knowledge of the formal number system. Jordan et al. (2007), following the same children from Jordan et al. (2006) into Grade 1, found differential patterns of growth for the linguistic and quantitative skills. With 7- to 10-year-old children, Durand et al. (2005) reported that both verbal ability and speeded magnitude comparison (e.g., Which is larger, 3 or 5?) predicted arithmetic performance. Krajewski and Schneider (2009) proposed a model that included distinct roles for linguistic knowledge and spatial attention in early numeracy development, although their model does not have a distinct quantitative pathway. In summary, existing research is generally consistent with the hypothesis that linguistic and quantitative pathways can be distinguished in early numeracy development.

Empirical support for a connection between spatial attention and mathematical learning comes from research on visual-spatial working memory. Working memory can be defined as the processing and storage requirements involved in complex cognitive tasks (Baddeley, 2002; Bull et al., 2008; DeStefano & LeFevre, 2004; Zentall, 2007). Researchers have explored the impact of specific working memory subsystems on children's mathematical performance, that is, the phonological loop (Swanson & Sachse-Lee, 2001; Wilson & Swanson, 2001) or the visual-spatial sketchpad (VSSP; Bull et al., 2008; Holmes, Adams, & Hamilton, 2008; McKenzie, Bull, & Gray, 2003; Rasmussen & Bisanz, 2005; Simmons, Singleton, & Horne, 2008). Some researchers have found that the VSSP is more important in mathematical performance for younger children, whereas the phonological loop is more important for older children (Holmes et al., 2008; Krajewski & Schneider, 2009; McKenzie et al., 2003). Thus, in younger children, measures of visual-spatial working memory may predict mathematical achievement independently of the linguistic or quantitative pathways.

> *Hypothesis 2: Linguistic, quantitative, and spatial attention pathways vary in their unique and relative contributions to later mathematical performance, depending on the demands of the tasks*

Because conventional tests of mathematical skills involve number system knowledge, the linguistic pathway is likely to be predictive of all mathematical outcomes. However, most conventional tests of mathematics presumably also require knowledge of numerical magnitude and skill at manipulating quantities. Furthermore, conventional tests typically engage attentional processes (DeStefano & LeFevre, 2004; Swanson, Jerman, & Zheng, 2008). The Pathways model predicts that to the extent that specific mathematical tasks involve different skills, the three pathways will vary in their unique and relative contribution to each task.

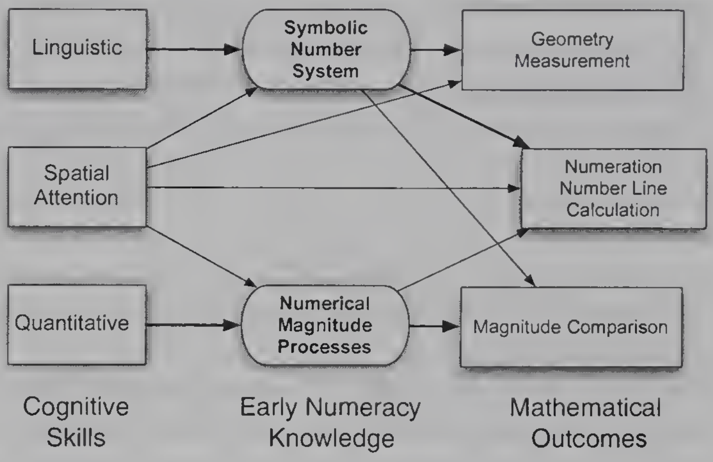

Figure 1. The Pathways model showing predicted relations among cognitive precursors, early numeracy skills, and mathematical outcome measures.

Figure 1 captures the hypotheses and predictions that arise from the Pathways model. Linguistic abilities form a skill pathway with children's symbolic number system knowledge. Quantitative abilities form a separate skill pathway linked with processing numerical magnitudes (i.e., quantity processing that does not require knowledge of the conventional number system). Spatial attention forms a third pathway. We assume that spatial attention will be important for the development of a variety of numerical and mathematical skills. As shown in the figure, we expected the three pathways to contribute differentially to the various outcomes that we assessed. Importantly, the figure reflects the general prediction from the model that the relative contribution of each pathway will depend on the task requirements. All outcomes should require some knowledge of the symbolic number system and hence the involvement of the linguistic pathway, but the quantitative pathway may not contribute uniquely for all outcomes.

Method

Data were drawn from a longitudinal project that spanned 4 years and included over 500 children and a wide variety of measures. In the present analyses, we focused on the 182 children who started the study in preschool (age 4) or kindergarten (age 5) and participated for 3 years. Several decisions guided choices of measures and analyses. First, we used standardized measures, based on age or grade norms as appropriate, whenever these were available. This decision allowed maximum comparability with other studies and provided a control for age-related effects. Second, for measures that did not have norms, we calculated z scores within age groups to use in correlational and regression analyses. Third, we focused on concurrent relations between (a) cognitive precursors and early numeracy measures from the 1st year of participation and (b) performance on conventional measures 2 years later.

Participants

A total of 196 preschool and kindergarten children were recruited from seven schools in three Canadian cities (Ottawa, Peterborough, and Winnipeg). Data were missing for 14 of these children on one or more measures in the 1st year of testing, and thus the present analyses are based on the 182 children (37 preschoolers and 145 kindergarteners) who had complete data for Year 1. The kindergarten children attended half-day classes in the schools. The preschool group attended half-day programs, either in the same schools (i.e., "junior" kindergarten in Ottawa and Peterborough) or in feeder preschools. Children in the preschool group (19 girls, 18 boys) ranged in age from 4:5 to 5:8 (years:months) at the time of the study, with a median age of 5:0. Children in the kindergarten group (70 girls, 75 boys) ranged in age from 5:4 to 6:6, with a median of 5:11 (including 1 boy who was 4:7 and had been allowed to start kindergarten 1 year early).

Two years later 122 of these children participated, 23 of the group who had started the study in preschool (11 girls, 12 boys) and 99 of the group who had started in kindergarten (44 girls, 55 boys). Attrition occurred because families moved ($n = 23$), consent was not obtained ($n = 24$), or the school declined to participate (one school, $n = 13$ children) and it was not possible to contact the families outside of the school. Thus, over 2 years the attrition rate because of all causes was 33%. A comparison of the children in the longitudinal sample and those who were not retained is presented as a preliminary analysis in the Results section.

Most of the children came from middle-class homes. The majority of families (87%) reported two adults living in the home. The majority of mothers had a university or postgraduate degree (56%) or had a diploma from a vocational college (18%). Only 2% had not finished high school. Most of the children spoke English at home (95%).

Materials and Procedures

Beginning in May of each year, children were tested by trained experimenters. Computer tasks and pencil-and-paper tasks were administered in two separate sessions lasting 15–30 min each or, in some cases, a single longer session. Tasks were performed in the same order in each session (paper or computer), but which session was conducted first varied because of the availability of experimenters and children.

Cognitive Precursors

Linguistic skills. Various aspects of linguistic development, such as phonological awareness, vocabulary, verbal reasoning, and listening comprehension (Aunola et al., 2004; Durand et al., 2005; Hecht, Torgesen, Wagner, & Rashotte, 2001; Krajewski & Schneider, 2009; Simmons et al., 2008), have been implicated as predictors of mathematical skill in the early school years. We hypothesized that receptive vocabulary would reflect children's ability to acquire vocabulary in the number system. Furthermore, acquiring the visual symbols (i.e., Arabic digits) and linking them to mental labels is similar to developing lexical or sublexical mappings when children are learning to read. Thus, we chose measures of vocabulary and phonological awareness to index linguistic skills.

Receptive vocabulary was measured with the Peabody Picture Vocabulary Test–Revised, Form B (Dunn & Dunn, 1997). This task is standardized by age with a mean of 100 and standard deviation of 15, and with a reported internal consistency (Cronbach's alpha) of .94. Phonological awareness was indexed by the elision subtest of the Comprehensive Test of Phonological Processing (Wagner, Torgesen, & Rashotte, 1999). Children hear a word and are asked to say the word again, but omitting a sound (e.g., brat without the /r/). The test is age standardized with a mean of 10 and a standard deviation of 3, with Cronbach's alpha for 5-year-olds of .90. All children completed these measures when they were in kindergarten.

Quantitative knowledge. We assumed that quantitative knowledge reflects a child's ability to evaluate and discriminate quantities with minimal additional cognitive requirements (see also Halberda et al., 2008; Landerl, Bevan, & Butterworth, 2004; Willburger, Fussenegger, Moll, Wood, & Landerl, 2008). On this view, one way to assess quantitative knowledge is to measure children's ability to compare numerosities of sets of objects and determine which has more (e.g., Halberda et al., 2008). Another is to use symbolic representations of quantity, that is, Arabic digits or words, in number comparison tasks (e.g., Durand et al., 2005; Landerl et al., 2004) or to ask children to do magnitude comparisons of digits versus small quantities (Which is larger, 3 or **? e.g., Koontz & Berch, 1996). In both of these approaches, quantity knowledge is measured via a comparison. We chose a third approach to assess quantitative knowledge. When asked to indicate the quantity of small sets of objects, people are faster and more accurate on set sizes of 1–3 or 4 than on set sizes of 5 or larger (Mandler & Shebo, 1982). Moreover, response latencies are similar on small sets, and increase linearly on sets greater than 4. These data are consistent with the view that children and adults use a rapid pattern-matching process, *subitizing*, on small sets and counting-based processes on larger sets. Researchers have suggested that subitizing is a reasonable index of children's quantitative knowledge (Desoete & Grégoire, 2006; Landerl et al., 2004; van der Sluis, de Jong, & van der Leij, 2004; Willburger et al., 2008).

Children were shown arrays of one to six dots and were asked to state "how many" dots as quickly and accurately as possible. Children initiated the trial by pressing the space bar. The trial ended when the child stated the numerosity of the set and the experimenter pressed a key and then typed the response. There were three trials of each array size, each in a different random pattern. The median subitizing latency was computed from the latencies of the nine trials showing one, two, and three dots.

The children completed this task each year, but because subitizing was considered a precursor skill, only Year 1 data were used for model testing. However, cross-year consistency of subitizing speed was of interest for reliability and validity. The test–retest correlation in the larger longitudinal study was $r(237) = .46$, $p < .001$, between the 1st and 2nd years, and $r(228) = .30$, $p < .001$, between the 1st and 3rd years.

Spatial attention. Existing research on the role of working memory in mathematical development has indicated that the spatial span task (also known as Corsi or block span) is a useful index of visual-spatial working memory in young children (Bull et al., 2008; Holmes et al., 2008; McKenzie et al., 2003; Rasmussen & Bisanz, 2005; Simmons et al., 2008). In this task, the experimenter indicates a series of locations by touching each one briefly. The participant attempts to reproduce the ordered sequence. In contrast to verbal measures, such as digit span, research with adults has shown that verbal strategies are unhelpful on the spatial span task (Ridgeway, 2006). However, spatial and executive working memory resources are often difficult to distinguish empirically (e.g., Miyake, Friedman, Rettinger, Shah, & Hegarty, 2001). Thus, the spatial span task may index specific spatial working memory capacity, nonverbal strategies, and more general attentional capacity (Bisanz et al., 2005; Rasmussen & Bisanz, 2005). For present purposes, we refer to this complex of skills as *spatial attention*.

Children were shown a set of nine lily pads arranged in a pseudorandom pattern. For each trial, a frog appeared on a sequence of the lily pads (1 s per pad). Next, the child replicated the series by pointing to the lily pads. The experimenter clicked on each location that the child pointed to and the computer recorded the path. Following a demonstration trial, children attempted two trials at each series length, beginning with a series of two appearances, and progressing up to a series of six appearances. When a child responded incorrectly on both sequences of a given length, the task was terminated. The score consisted of the total number of correct sequences (maximum 12). Internal consistency, based on the two sequences at each series length, was .70 (Cronbach's alpha). The test–retest correlation between performance between the 1st and 2nd years (in the longitudinal study) was $r(182) = .44$, $p < .001$, and between the 1st and 3rd year was $r(228) = .56$, $p < .001$. Thus, children showed reasonable stability across years for this measure. For analyses of outcome measures, an average span was calculated using scores for all 3 years, or for the 1st and 3rd year for the 9 children who were missing a span score in Year 2. The internal reliability of this cross-year measure was .72 (Cronbach's alpha).

Early Numeracy Skills

We assumed that early numeracy skills (i.e., skills that children acquire before they start formal schooling) generally revolve around children's knowledge of numbers and quantities. We selected two tasks, number naming and nonlinguistic arithmetic, which capture important aspects of early numeracy and that we assumed would be maximally different in terms of requiring the quantitative versus the linguistic pathways.

Number naming (i.e., saying "twelve" when presented with "12") was assumed to reflect children's familiarity with Arabic number symbols. This task requires children to map Arabic digits to a phonological representation but does not require them to access the quantity or magnitude associated with the symbol (although, with practice, quantity may be accessed automatically). In Dehaene et al.'s (2005) model, naming numbers invokes internal representations associated with a linguistic code.

Children named Arabic numbers presented on the computer screen one at a time, in the following order: 3, 1, 7, 2, 9, 12, 15, 20, 22, 37, 64, 77, 95, 101, 210, 688, 1,500, 4,302. The task was terminated after three consecutive errors. Errors included instances in which child named the digits in numbers greater than 9 (e.g., said "one-five" for the number 15), said "I don't know," or produced only part of the number correctly (e.g., said "thirty-five" for the number 37). The score consisted of the number of correct responses (maximum 18).

In the nonlinguistic arithmetic task (Huttenlocher, Jordan, & Levine, 1994; Levine, Jordan, & Huttenlocher, 1992), children are shown an initial quantity that is then hidden. They watch as a transformation is applied to the hidden objects (i.e., some are visibly removed or added) and then reproduce the hidden number with their own objects. This task requires children to represent and mentally manipulate quantities, but does not require them to label those quantities with number names or to link the quantities to the Arabic symbols.

Children began with three practice trials in which the experimenter lined up a set of animals in front of a barn and then pushed them into the barn so that they were hidden from the child. The child was asked to model the number of hidden animals by using their set of animals. On the first three trials, the child simply matched the number of animals in the barn (3, 1, 5). On the next three trials, children were given addition problems: After the original set was moved to the barn, more animals were added (1 + 2, 2 + 3, 2 + 2). On the last three trials, children were given subtraction problems: After the original set was moved to the barn, some animals were moved out (2 − 1, 4 − 2, 5 − 4). The problems were presented in the same order for each child. The maximum possible score was 9, 3 for each type of problem. Percentages of correct trials were used in the analyses.

Outcome Measures

Children completed the outcome measures in the 3rd year of the project.

Conventional tests of mathematical knowledge. These tests included the Numeration, Geometry, and Measurement subtests from the KeyMath Test–Revised (Connolly, 2000) and the Calculation test from the Woodcock–Johnson Tests of Achievement–Revised (WJ–R; Woodcock & Johnson, 1989). These tasks were expected to capture many of the mathematical skills that children are assumed to learn in the first 2 years of school. Furthermore, these tasks were chosen to represent a range of measures that, although all central to mathematics, might vary in the extent to which they required linguistic versus quantitative knowledge.

The KeyMath Test has Canadian norms and the subtests are consistent with curricular guidelines. The Numeration subtest assesses quantity, order, and place value. Most of the items in the range for these children require knowledge of the symbolic number system. The Measurement subtest includes a variety of questions for which children are asked to compare quantities (e.g., size, extent, volume, mass) and choose the larger or smaller. The Geometry subtest includes some vocabulary items (e.g., sphere), some questions that require language-mediated processing of spatial arrays (e.g., point to the fourth-last item in the third row of the table), and some sequencing and patterning questions. For these three tests, grade-scaled normative scores were used ($M = 10$, $SD = 3$).

The Woodcock Calculation test is a traditional paper-and-pencil measure of factual and procedural computation skill (Woodcock & Johnson, 1989). Testing stopped after six incorrect or "I don't know" answers. This test has a median reliability of .85 and a 1-year test–retest correlation of .89 for Grades 2 through 4.

Research-based measures of mathematical knowledge. Children completed two additional mathematical measures, administered on laptop computers. These measures are commonly used in the research literature on children's mathematical development. In contrast to the conventional tests, intended to tap a range of knowledge, these research-based measures tap specific knowledge in greater detail.

The Number Line task requires that children select the appropriate position on a number line for numbers between 0 and 1,000. This number line measure is intended to capture both number system knowledge and children's internal quantity representations (Opfer & Siegler, 2007; Siegler & Booth, 2004; Siegler & Opfer, 2003; cf. Moeller, Pixner, Kaufmann, & Nuerk, 2009). We hypothesized that this task relies heavily on the linguistic pathway because it requires understanding of symbolic numbers but may also index the extent to which children have coordinated symbolic and numerical magnitude knowledge. Children completed this task when they were in Grade 2.

Children initiated each trial by pressing a Go button, which displayed the target number and cursor in the image of a car. They used the mouse to move the cursor to the position on the displayed number line. Endpoints of the line were labeled 1 and 1,000. The computer recorded the location and the solution latency. Stimuli were chosen based on Laski and Siegler (2007) and were balanced with four targets between 0 and 100, four between 900 and 1,000, two targets from each other decade and distances matched from the endpoints. The targets [and matching items] were: 6 [994], 18 [982], 59 [991], 97 [903], 124 [876], 165 [835], 211 [789], 239 [761], 344 [656], 383 [617], 420 [580], 458 [542], and 500. Order of the 25 trials was randomized separately for each child.

Regression was used to calculate the relation between the actual values of the presented numbers and the locations that the child chose. Perfect performance would occur if each presented number were placed at the appropriate location (e.g., 500 at the center of the line). Various indices of performance can be calculated. In previous work, Siegler and colleagues have used mean r^2 values from linear regressions (regressing line location on actual number) as the index of fit. In our data, examination of the distribution of r^2 values showed a significant deviation from normality, with a value for skew of −.98 ($SE = .25$; 95% CI = .48). An alternative index is the slope of the regression line. Perfect placement of each number on the line would result in a slope of 1.0. Random placement would result in slopes close to 0. In the present research, slope values were distributed normally, with a value of skew of −.21 ($SE = .25$, 95% CI = .49). To allow comparison with previous work, analyses of both r^2 and slope values are presented.

Children also completed a symbolic magnitude comparison task (Landerl et al., 2004). Symbolic magnitude comparison is assumed to require both linguistic and quantitative knowledge (Holloway & Ansari, 2009). Children viewed pairs of single-digit numbers that varied in size and indicated which number was "more" by pressing an appropriate key. Of the 40 trials, on 20 the numerically larger number was also physically larger (i.e., congruent trials) and on the other 20, physical size and magnitude were incongruent. The split between the numbers was 1 for 24 trials (e.g., 2 vs. 3) and 5 for 16 trials (e.g., 2 vs. 7). Two practice trials preceded the experimental trials. Children viewed one of two randomized lists.

Children pressed the space bar to start the trial. After a 500-ms delay, the two numbers appeared simultaneously. The trial terminated after the child responds or if 3 s elapsed with no response. Response times and accuracy were recorded. The percentage of correct trials was used as the outcome measure.

Word reading. Children completed the Word Identification subtest of the Woodcock Reading Mastery Tests–Revised/Normative Update, Form G (Woodcock, 1998). Word Reading was used to examine the possibility that all complex cognitive tasks, not just mathematical ones, would involve all of the linguistic, spatial attention, and quantitative pathways. In accord with the predictions of the pathways model, we hypothesized that only the linguistic pathway, and not the quantitative pathway, would be related to word reading performance. In this test, children read isolated words. Split-half reliability coefficients for Grade 1 children are reported as .98. Scores are standardized by grade to have a mean of 100 and a standard deviation of 15. All children completed this test in Grade 1.

Results

Means, standard deviations, and correlations among tests are shown in Table 1 for the cognitive precursors and early numeracy skills, measured in Year 1, and in Table 2 for the outcome measures, measured in Year 3. Gender was correlated only with number naming and with the Number Line task. Boys named more numbers correctly than did girls, with mean z scores of .18 and −.31, respectively, $t(180) = -3.13$, $p < .001$. On the Number Line task, girls had smaller mean r^2 values than boys (.62 vs. .76), $t(93) = -2.77$, and flatter slopes (.48 vs. .61), $t(93) = 2.98$, $ps < .01$. Given these differences, gender was controlled in all regressions.

The expectation that children would subitize quantities up to 3, and count for 4, 5, or 6 was supported by accuracy and latency data. Both preschoolers and kindergarten children were virtually perfect on arrays of 1, 2, or 3 (98.3% and 99.5% correct, respectively). However, on arrays of 4–6, both groups made some errors, and younger children made more than older children (79% vs. 91%), $t(57.0) = -3.03$, $p < .01$. Median latencies were analyzed in a 2 (grade: preschool, kindergarten) × 6 (array size: 1–6) mixed analysis of variance. Data are shown in Figure 2. Younger children responded more slowly than older children (3,176 vs. 2,557 ms), $F(1, 172) = 20.68$, $MSE = 2{,}969{,}000$, $\eta_p^2 = .107$. Latencies increased with array size, $F(5, 860) = 300.77$, $MSE = 797{,}142$, $\eta_p^2 = .636$, and grade interacted with array size, $F(5, 860) = 5.39$, $\eta_p^2 = .03$. Children's latencies on arrays of one and

two dots were not different at either age level. However, three dots were named more slowly than two dots for both the preschool and the kindergarten children. Preschool children were slower on all array sizes than kindergarten children, but the differences were larger for arrays of 4, 5, and 6 than for 1, 2, and 3. Median latencies on arrays of 1–3 were used as the index of subitizing latency.

The performance of children who only participated in Year 1 and those who were retained throughout the study was compared for the six Year 1 measures. Only two differences were notable. First, among the preschool children, those who dropped out had somewhat slower subitizing latencies than those who continued (1.5 vs. 2.0 s), $t(14.8) = 2.12$, $p = .052$. Inspection of the data indicated that a few children in the group who were not retained had very slow latencies. Second, among kindergarten children, those who dropped out had lower scores on the nonlinguistic arithmetic task than those who continued in the study (6.8 vs. 7.8), $t(71.6) = 2.92$, $p < .01$. Inspection of the data suggests that there were relatively more children with perfect scores in the retained group than in the group who were not retained but that the lower range of performance was not restricted. These differences were unlikely to have biased the results in favor of our hypotheses but they might have resulted in an underestimate of the importance of the quantitative pathway.

Tests of the Pathways Model

Hypothesis 1: Linguistic, quantitative, and spatial attention pathways contribute independently to early numeracy

As shown in Table 1, all four precursors (vocabulary, elision, subitizing, and spatial span) were significantly correlated with both early numeracy measures, number naming, and nonlinguistic arithmetic. Consequently, multiple regressions were used to test the model, as shown in the last two columns of Table 1. These show strong support for the four predictions based on Hypothesis 1. First, linguistic skills (vocabulary, elision) predicted unique variability (as reflected by semipartial correlations) in number naming but not in nonlinguistic arithmetic. Second, quantitative skill (subitizing latency) predicted significant unique variability in nonlinguistic arithmetic but not in number naming. Third, although the simple correlation between number naming and nonlinguistic arithmetic was significant, neither accounted for unique variability in the corresponding regression. Fourth, spatial attention was a unique predictor of variability in both early numeracy measures. Thus, the patterns of performance support the view that linguistic and quantitative pathways are distinct predictors of early numeracy skills that assess number system knowledge and numerical magnitude processing, respectively. Spatial attention forms a third independent pathway that is related to both types of early numeracy performance.

We used factor analysis to compute separate linguistic and quantitative predictors for use in longitudinal analyses. The cognitive precursors (elision, vocabulary, subitizing speed) and the early numeracy measures (number naming and nonlinguistic arithmetic) were entered into a principal components analysis. Two factors emerged that accounted for 63% of the variance. The first factor included the linguistic measures, with factor loadings of .76, .74, and .76 for elision, vocabulary, and number naming, respectively. The second factor included subitizing latency and nonlinguistic arithmetic, with loadings of −.81 and .79. Factor scores were used in the longitudinal regressions to index the linguistic and quantitative pathways.

Hypothesis 2: Linguistic, quantitative, and spatial attention pathways vary in their unique and relative contributions to later mathematical performance, depending on the demands of the tasks

Table 3 contains results from multiple regressions in which gender and predictors for each of the three pathways are used to account for variability in performance on conventional and research-based mathematical outcomes, as well as word reading. Three observations are particularly noteworthy. First, the proportion of variability accounted for by these predictors is substantial, ranging from .26 to .56 for the mathematical outcomes. Second, the amount of variability predicted uniquely by each pathway varies, depending on the outcome. For example, all three pathways are implicated in performance on Numeration, Calculation, and the Number Line tasks, but the quantitative pathway is not involved in Geometry and Measurement and spatial attention is not involved in Magnitude Comparison. Perhaps not surprisingly, the linguistic pathway alone accounts for significant variability in Word Reading, but it also is the only variable to be implicated in all of the mathematical outcomes. Third, semipartial correlations are higher for the linguistic pathway than for the quantitative and spatial attention pathways for six of seven mathematical outcomes, indicating that the general sorts of language-related skills reflected in elision, vocabulary, and number naming are a key component in tests that typically are assumed to measure mathematical knowledge and skill. Thus, all three pathways are involved in perfor-

mance on some, but not all mathematical tasks, and the degree of involvement varied across tasks.

Discussion

We developed and tested a model of the relations among cognitive precursors, early numeracy knowledge, and the subsequent performance of conventional and research-based tests of mathematical skill. The first hypothesis was that linguistic, quantitative, and spatial attention would form separate skill pathways. In support of this hypothesis, we found that vocabulary and elision (linguistic skills) were related to number naming, whereas subitizing latency (quantitative skill) was related to nonlinguistic arithmetic. Linguistic skills did not predict nonlinguistic arithmetic and subitizing did not predict number naming, supporting the proposed distinction between these pathways. Accordingly, numerically relevant linguistic and quantitative skills formed two distinct factors for these young children.

Spatial attention showed significant relations to both number naming and processing of numerical magnitude, in support of a third pathway. The finding that spatial attention is related to the development of a variety of early mathematical skills is consistent with recent findings in which similar measures of nonverbal working memory were related to children's mathematical performance in the first few years of school (Bull et al., 2008; Holmes et al., 2008; Krajewski & Schneider, 2009; Simmons et al., 2008). More generally, attentional processes may be important in children's ability to manage the complex requirements of mathematical tasks (Geary, Hoard, Byrd-Craven, Nugent, & Numtee, 2007).

There was also support for the second hypothesis that the roles of the linguistic, quantitative, and spatial attention pathways would vary depending upon the mathematical outcomes. The spatial attention pathway accounted uniquely for moderate amounts of variability on six of seven mathematical tasks but was never the dominant predictor. The linguistic pathway accounted uniquely for variability in all of the mathematical outcomes but the strength of the relation varied such that it was weakest with magnitude comparison and strongest with numeration. Thus, as predicted, the relative importance of the pathways depends on the extent to which number system and numerical quantity knowledge is used in the mathematical task. For example, magnitude comparison requires only that children know the symbol–quantity correspondence for single-digit numerals from 1 to 9. In contrast, the numeration test requires knowledge of three-digit numbers, including advanced understanding of place value. Similarly, the linguistic pathway was a strong predictor of the linearity of children's number line knowledge for the numbers from 1 to 1,000. This task requires children make a connection between symbolic representations (e.g., 864) and a spatial extent. They would not be able to attempt the task without a reasonably good understanding of the Arabic symbols for numbers to 1,000.

For the quantitative pathway, the strength of the relation with the outcomes overall was modest. Of interest were the relative patterns for the linguistic and quantitative pathways. Here, two extremes emerged. For geometry and measurement, the linguistic pathway was uniquely predictive but the quantitative was not, even though the quantitative pathway was correlated with performance on these outcomes. In contrast, for magnitude comparison, the quantitative pathway was numerically but not statistically more strongly related to performance than the linguistic pathway. This result is consistent with some existing work suggesting that performance on the magnitude comparison task reflects children's skill in linking together symbolic and nonsymbolic numerical processes (DeSmedt et al., 2009; Holloway & Ansari, 2009; Mundy & Gilmore, 2009; Rousselle & Noël, 2007). The finding that linguistic, quantitative, and spatial attention pathways vary in their relation to mathematical outcomes has two notable implications. First, the Pathways model could prove helpful in understanding why some children might do well at one mathematical task but not another. Second, the model may prove useful for determining the psychological demands of tasks that are designed ostensibly to measure mathematical skill.

Connections to Research With Special Populations of Children

The Pathways model is consistent with research on special populations of children who have deficits related to mathematics. Using the model, many children can be grouped according to whether their deficits are in linguistic or quantitative processing. For example, children with specific language impairments (SLI) do poorly on mathematical tasks that have a linguistic component (and thus involve knowledge of the number system) but perform similarly to peers without SLI on tasks where quantitative knowledge is most relevant (Donlan, 2007). In contrast, children with Williams syndrome (who have both spatial difficulties and mathematical delays) appear to use their relatively stronger linguistic skills to do mathematical tasks and hence show specific patterns of weaknesses on tasks that require quantitative processing (Ansari et al., 2003). Similarly, children with spina bifida and cerebral palsy, who have motor deficits and compromised mathematical skills, appear to have deficits in the quantitative pathway (Barnes et al., 2005). Thus, the pathways model will be useful in understanding this dissociation in linguistic and quantitative performance for children with specific deficits in mathematics. We also speculate that children who have a specific mathematics disability (i.e., dyscalculia) might show particular weakness in the quantitative pathway, but overall average or better performance in the linguistic pathway. In contrast, children who show deficits in both mathematics and reading (i.e., are dyscalculic and dyslexic) are weak in both pathways (Jordan et al., 2007; Willburger et al., 2008). Finally, children with attention deficit hyperactivity disorder often have mathematical difficulties (Zentall, 2007). According to the pathways model, we might expect those children to have deficits in the spatial attention pathway, but show typical variability in relevant linguistic and quantitative skills.

Future Considerations

Further work is needed to refine and develop the Pathways model theoretically, empirically, and methodologically. In the Pathways model, it was reasonable to use spatial span to index attention because we linked our model to Dehaene's neuropsychological account of the parietal circuits that support numerical processing. However, working memory and attentional processing more generally involve the coordination of processes and knowledge that go beyond the parietal circuits. For example, central executive resources also involve the frontal lobe (Bull et al., 2008; Espy & Bull, 2005). Furthermore, working memory is assumed to involve coordination of information from the world and from memory. As the Pathways model is further developed to encompass learning trajectories and related processes, a more detailed account of how working memory and related attentional processes are important will become critical (Geary et al., 2007; Swanson et al., 2008).

The issue of how to operationalize the core quantity skill, as processing of small exact numerosities versus as approximate magnitudes (or both), also remains an important area for further research. Our decision to operationalize quantitative knowledge as subitizing latency (i.e., efficiency of identifying small exact quantities) was based on Butterworth's view that processing exact numerosities is the source of mathematical difficulties for children with dyscalculia (Butterworth, 1999, 2005). An alternative view is that mathematical difficulties reflect limitations in children's speeded access to the links between quantities and number names (see also Holloway & Ansari, 2009; Koontz & Berch, 1996; Rousselle & Noël, 2007). Thus, it may be the ability to create a mapping between symbolic knowledge and numerical quantity representations that is crucial in mathematical learning (Ansari, 2008). Furthermore, subitizing has not been universally accepted as a core quantity skill. An alternative view is that subitizing is a visual–attentional process that is not specific to numerical tasks (see also Trick & Pylyshyn, 1994). For example, children with cerebral palsy, especially those with right-hemisphere damage, are impaired on both subitizing and counting relative to normally developing children and have impaired pattern recognition processes that are not numerically specific (Arp & Fagard, 2005). Arp and Fagard (2005) concluded that counting and subitizing both reflect global, rather than numerically specific, processes. In this view, subitizing processes may be recruited to support quantitative tasks and thus become more closely related to quantitative processing over time. Clearly, more evidence is needed to determine the relations among subitizing, nonsymbolic magnitude comparisons, and the development of various mathematical abilities and knowledge (Ansari, 2008; Holloway & Ansari, 2009; Rousselle & Noël, 2007).

As formulated, the Pathways model does not address the question of how knowledge from the linguistic and quantitative pathways is integrated, although working memory may play an important role in this process (Krajewski & Schneider, 2009; Swanson et al., 2008). Children's knowledge of mathematics, at least for normally developing individuals, presumably reflects the interplay of linguistic and quantitative skills because both are recruited by most complex mathematical tasks.

Conclusion

We proposed and tested a model of how cognitive skills are implicated in the development of children's mathematical knowledge. The Pathways model includes three forms of knowledge: quantitative, linguistic, and spatial attention, and it specifies the initially distinct role each of these plays in early numeracy acquisition. We showed that the three pathways relate differentially to conventional tests of mathematical knowledge, in support of the view that mathematical development is componential. The model connects research from adults, neuroimaging, clinical populations, and normal development. Furthermore, across various mathematical outcomes (e.g., geometry, measurement, calculation, numeration), the Pathways model highlights the need to understand the fundamental underlying skills that contribute to all of these specific domains.

How 15 Hundred Is Like 15 Cherries: Effect of Progressive Alignment on Representational Changes in Numerical Cognition

Clarissa A. Thompson
The University of Oklahoma

John E. Opfer
The Ohio State University

How does understanding the decimal system change with age and experience? Second, third, sixth graders, and adults (Experiment 1: N = 96, mean ages = 7.9, 9.23, 12.06, and 19.96 years, respectively) made number line estimates across 3 scales (0–1,000, 0–10,000, and 0–100,000). Generation of linear estimates increased with age but decreased with numerical scale. Therefore, the authors hypothesized highlighting commonalities between small and large scales (15:100::1500:10000) might prompt children to generalize their linear representations to ever-larger scales. Experiment 2 assigned second graders (N = 46, mean age = 7.78 years) to experimental groups differing in how commonalities of small and large numerical scales were highlighted. Only children experiencing progressive alignment of small and large scales successfully produced linear estimates on increasingly larger scales, suggesting analogies between numeric scales elicit broad generalization of linear representations.

The ratio structure of the decimal system—where "1" denotes a quantity 1/10 of 10, "10" a quantity 1/10 of 100, "100" a quantity 1/10 of 1,000, and so forth—may apply to an infinity of numbers, but even over a lifetime, experience of symbolic numbers is finite. And more, experiences are also systematically biased, with numerals in the first order of magnitude (1–9) appearing much more frequently than numerals in the second order (10–99), which occurs more frequently than in the third order (100–999), and so forth (Dehaene & Mehler, 1992). This cross-linguistic regularity in frequency of symbolic numbers—observed in languages as diverse as American English, Catalan, Dutch, French, Japanese, Kannada, and Spanish—has been observed across forms of notation (Arabic or written number words), for cardinal numbers (1, 2, 3) as well as ordinals (first, second, third), and in both text and speech.

This cross-linguistic regularity in frequency of symbolic numbers has two interesting implications for how children might develop their representations of numerical magnitude. The first developmental implication is that relative frequencies of numerals in the environment place a constraint on how broadly children extend their understanding of the decimal system. Specifically, children learning to map numerals to magnitudes would be expected to fail to realize that ratios that hold at smaller, more familiar orders of magnitude (e.g., relative magnitudes of 15 cherries and 100 cherries) extend to larger orders of magnitude (e.g., relative magnitudes of 1,500 and 10,000) with which they are less familiar.

The second implication is that if developing representations of large numerical magnitudes are constrained by poverty of input described by Dehaene and Mehler (1992), no inherent cognitive constraint would prevent rapid and broad representational changes from occurring in children. The crucial source of change in this account is children encountering information that relations among numbers at large orders of magnitude are similar to relations at small orders of magnitude (e.g., 150:1,000::15:100), much like relations at small orders of magnitude are similar to each other regardless of units involved (e.g., 15 cherries:100 cherries::15 pears:100 pears). If true, such findings

---

The authors would like to thank the administration, teachers, students, and parents from the Worthington School District in Columbus, OH, as well as the Bentworth School District in Bentleyville, PA. Further, the authors would like to thank Julia Kennedy for her help in data collection, Chris Young for his contributions to the "change point" analyses in the General Discussion section, and anonymous referees who provided helpful comments on earlier versions of the manuscript. Portions of these data were presented at the 2007 meeting of the Cognitive Development Society as well as the 30th annual conference of the Cognitive Science Society.

Correspondence concerning this article should be addressed to Clarissa A. Thompson, Department of Psychology, The University of Oklahoma, 455 W. Lindsey Street, Dale Hall Tower, Room 727, Norman, OK 73019. Electronic mail may be sent to cat3@ou.edu.

would be scientifically important because it could reconcile two sets of seemingly contradictory findings—slow rate of representational changes observed in cross-sectional studies (e.g., Siegler & Opfer, 2003; logarithmic-to-linear switch in numeric representations between second and fourth grade on 0–1,000 number line problems) and one-trial representational changes observed in microgenetic studies (e.g., Opfer & Siegler, 2007; second graders' adoption of a linear representation after maximally discrepant feedback is presented). That is, representational change in the domain of numbers may be driven by children's ability to draw an analogy between small and large orders of magnitude, and previous research has indicated that direct feedback may highlight this analogy of the decimal system for children (Opfer & Siegler, 2007).

Previous evidence supporting the first conjecture about children's developing understanding of this property of the decimal system—as well as potential for improvement coming from comparison of small and large orders of magnitude—comes from interindividual variability in magnitudes children associate with a given number. When asked to place numbers on a number line flanked by 0 and 100, for example, second graders provided Siegler and Opfer (2003) with a set of estimates that were highly accurate and increased linearly with numeric value. When asked to place the same numbers on a number line flanked by 0 and 1,000, however, these same children provided estimates that were much less accurate, with estimates increasing logarithmically with numeric value. Thus, across contexts, the magnitude "15" was estimated as having different relations to 100 and 1,000. Moreover, this variability appeared to reflect variability in children's thinking about numeric magnitude rather than "noise" attributable to measurement error: Given no feedback, children's numerical magnitude estimates on a number line are highly stable from trial to trial (Opfer & Siegler, 2007; Opfer & Thompson, 2008; Thompson & Opfer, 2008).

To address these two implications more directly, Experiment 1 was designed to test how broadly children spontaneously apply linear representations on number lines with large numeric anchors (e.g., 0–1,000, 0–10,000, and 0–100,000). To test whether analogy could serve as a mechanism of developmental change across numeric representations, Experiment 2 examined whether progressive alignment—a means of fostering analogies in young children (Gentner, Loewenstein, & Hung, 2007; Kotovsky & Gentner, 1996)—led numeric representations used at small numerical scales (0–100) to be generalized to progressively larger numerical scales (0–1,000, 0–10,000, and 0–100,000) simply by highlighting perceptual similarities across these numeric contexts.

In the next sections, we will detail (a) development of numeric representations across the life span, (b) analogy as a mechanism of developmental change across numeric representations, and (c) more specific empirical questions that were examined in the present studies.

Development of Numerical Representations

Children normally improve their understanding about magnitudes denoted by symbolic numerals across a wide range of tasks (e.g., number line estimation, number categorization, magnitude judgments, etc.). Development of numerical representations appears to occur iteratively, with parallel developmental changes occurring over many years and across many contexts (Siegler, Thompson, & Opfer, 2009). For example, sixth graders' estimates on 0–1,000 number lines increase linearly (Siegler & Opfer, 2003), whereas second graders' estimates increase logarithmically (Opfer & Siegler, 2007; Opfer & Thompson, 2008; Siegler & Opfer, 2003; Thompson & Opfer, 2008). On 0–100 number lines, second graders' estimates increase linearly (Geary, Hoard, Byrd-Craven, Nugent, & Numtee, 2007; Geary, Hoard, Nugent, & Byrd-Craven, 2008; Siegler & Booth, 2004; Siegler & Opfer, 2003), whereas kindergartners' estimates increase logarithmically (Siegler & Booth, 2004). Asked to estimate 0–10 chips from a pile of chips, kindergartners' estimates increase linearly, but preschoolers' estimates increase logarithmically (Opfer, Thompson, & Furlong, 2010). Further evidence for logarithmic-to-linear shifts in numerical magnitude representations have also been discovered when (a) children were asked to estimate candies in a container, (b) estimate salaries given in fractional notation, (c) provide answers to arithmetic problems, (d) make measurements of novel units, and (e) categorize and compare symbolic numbers (Booth & Siegler, 2006; Laski & Siegler, 2007; Opfer & DeVries, 2008; Opfer & Thompson, 2008; Thompson & Opfer, 2008).

Children's initial expectations that numerical magnitudes increase logarithmically are theoretically interesting because these expectations are consistent with Fechner's law. That is, just as sensations increase logarithmically with stimulus intensity (Fechner's law), representations of numeric magnitude also increase logarithmically with actual value (Dehaene, 2007). For instance, the difference between 1 and 10 cherries seems larger (or is more quickly detected) than the difference between 101 and 110 cherries, much as these numbers would be spaced on a logarithmic ruler (Dehaene, Dehaene-Lambert, & Cohen, 1998). This logarithmic representation of numerical magnitude is not unique to young children making estimates on number lines but is widespread across tasks (estimation of set sizes, numeric comparisons, random number generation, and economic games), across species (pigeons, rats, nonhuman and human primates), and across age groups (infants, children, and time-pressured adults; Banks & Hill, 1974; Brannon, 2005; Feigenson, Dehaene, & Spelke, 2004; Furlong & Opfer, 2009; Gallistel & Gelman, 1992; Moyer & Landauer, 1967; Roberts, 2005; Xu & Spelke, 2000).

Children's learned expectations that numerical magnitudes increase linearly are not just theoretically interesting but also have practical effects on their school achievement. For instance, linearity of children's number line estimates correlates strongly with how quickly they compare magnitudes (e.g., is 5 or 7 greater; Laski & Siegler, 2007), their ability to learn solutions to unfamiliar addition problems (Booth & Siegler, 2008), and their overall scores on mathematics achievement tests (Booth & Siegler, 2006; Siegler & Booth, 2004). Playing numeric board games (akin to Chutes and Ladders) has also been shown to impact preschoolers' ability to compare numerical value and to produce accurate answers to arithmetic problems (Griffin, Case, & Siegler, 1994; Ramani & Siegler, 2008; Siegler & Ramani, 2008, 2009). Thus, not only does the development of linear representations of numerical magnitude present an interesting scientific problem, it is also one with important educational consequences, an importance underlined by recommendation of the National Mathematics Advisory Panel to embrace practices that foster ''number sense,'' including ability ''to estimate orders of magnitude'' (U.S. Department of Education, 2008, p. 18).

Analogy as a Mechanism of Developmental Change Across Numeric Representations

By what mechanism might children abandon use of a logarithmic representation of numerical magnitude for use of a linear representation? Across many areas of cognitive development, an important mechanism for representational change is analogy, where elements in a target domain may share structural relations with a base domain despite lack of perceptual overlap among elements in the target and base domains (Chen & Klahr, 1999; Gentner et al., 1997; Holyoak & Thagard, 1995; Opfer & Siegler, 2004, 2007).

Although young children may initially have difficulty solving analogical reasoning problems (see Abdellatif, Cummings, & Maddux, 2008, for a recent review of the factors affecting the development of analogical reasoning in young children), a number of factors can improve analogical reasoning in children such as: (a) asking children to solve problems with familiar examples or familiar relations (e.g., loaf of bread:single slice of bread::lemon:___; Goswami & Brown, 1990), (b) providing direct instruction on higher order relations through the use of relational language (e.g., ''Daddy, Mommy, and Baby'' for sizes big, medium, and small; Rattermann & Gentner, 1998), (c) explaining classic analogies of the format A:B::C:D (e.g., noting the relation between A and B and the similarity between A and C and B and D; Alexander, Willson, White, & Fuqua, 1987), (d) training children to solve a base problem and then asking them to transfer this knowledge to solve a related target problem (e.g., children are told a story about a genie who moves jewels from one bottle to another by rolling a ''magic carpet'' into a tube shape, and then the children are asked to solve the problem of moving gumballs from one bowl to another; Holyoak, Junn, & Billman, 1984), and (e) comparing across various instances (e.g., Gentner & Namy, 1999).

Structure-mapping theory (Gentner, 1983) guides our understanding of children's analogical reasoning ability in the current experiments. According to structure-mapping theory, children form analogies by aligning representational elements between a base and target domain. This alignment process facilitates transfer of information from base to target through children's comparison of surface-level features. This comparison process leads to subsequent highlighting of common underlying relational structure shared by base and target (Kurtz, Miao, & Gentner, 2001).

In progressive alignment (Gentner et al., 2007; Kotovsky & Gentner, 1996)—a specific instantiation of structure-mapping theory principles—comparisons made between highly similar elements can promote subsequent analogical matches of lower overall similarity. Analogical matches are thus promoted because the process of aligning surface-level elements highlights common underlying relational structure. The alignment process makes this structure more salient and easily mapped from base to target domain even when participants are presented with less surface-similar matches.

According to Kotovsky and Gentner (1996), progressive alignment acts as a mechanism of representational change by allowing children to make similarity comparisons over concrete, perceptual similarities (e.g., monotonic increase in size across differently shaped stimuli). Then, these similarity comparisons facilitate children's ability to notice higher order relational commonalities across stimuli possessing fewer surface-level features in common (e.g., increase in size as compared to saturation of color across differently shaped stimuli). Thus, progressive alignment allows children to recognize "richer and deeper" abstract relational similarity uniting their mental representations that may not have been immediately apparent before similarity comparisons were made (Kotovsky & Gentner, 1996).

Our general perspective on representational change, drawn from computational models of cognition (Doumas, Hummel, & Sandhofer, 2008; Gentner, 1983; Hummel & Holyoak, 2003), historical changes in scientific concepts (Gentner et al., 1997; Holyoak & Thagard, 1995), and microgenetic studies of children's concept learning (Opfer & Siegler, 2004, 2007) immediately suggested analogy as a candidate mechanism for development of numerical representations. This hypothesis seemed especially likely to be true for number line estimates, where structure of elements in a number line problem (e.g., relation between right anchor and number to be estimated) offers a systematic regularity over orders of magnitude (e.g., 150:1,000::15:100).

Analogy was also suggested as a candidate mechanism of representational change for second-grade students in a recent number line training study conducted by Opfer and Siegler (2007). Although these second-grade students produced a logarithmic series of estimates on 0–1,000 number lines during pretest, when children received feedback on the placement of 150 (maximally discrepant point between logarithmic and linear functions forced to pass through 0 and 1,000), children immediately generated a linear series of estimates for all other numbers in the 0–1,000 numeric scale that were tested. This abrupt and broad generalization of learning—characteristic of analogical mapping more broadly (Chen & Klahr, 1999; Gentner, Holyoak, & Kokinov, 2001; Holyoak & Thagard, 1995; Opfer & Siegler, 2004)—led Opfer and Siegler to speculate that children had improved their performance by mapping commonalities between the less familiar, larger scale (0–1,000) to the more familiar, smaller scale (0–100) where children already possessed a linear representation.

In this article, we provided a novel test of Opfer and Siegler's (2007) hypothesis that analogy provides a mechanism for developmental changes in representations of numerical magnitude. Our test was unique in two important respects. First, if children can draw an analogy between 0–100 and 0–1,000 number line problems, feedback that Opfer and Siegler provided in the 0–1,000 scale would not be necessary for children to improve their performance on those problems. To test this issue, our strategy for eliciting analogies from children was to manipulate factors that would lead to comparisons of number line problems, and we otherwise avoided giving children feedback on target problems. Second, if children can extract general structural relations hypothesized by Opfer and Siegler (i.e., 150:1,000::15:100), they should generalize far outside the training space (e.g., from a 0–100 number line to a 0–100,000 number line), an issue that Opfer and Siegler did not address.

Further, we have proposed that possession of a numeric analogy between familiar, small numeric scales (0–100) and unfamiliar, larger numeric scales (0–1,000 and larger) can prompt children to scale up a linear representation of number to unfamiliar scales. Thus, familiarity with numeric context (0–100) plays an important role in our explanation of analogy as a mechanism of representational change, but another model of children's estimation performance, the segmented linear model (Ebersbach, Luwel, Frick, Onghena, & Verschaffel, 2008), suggests that a very different type of familiarity affects children's estimates.

According to Ebersbach et al.'s (2008) segmented linear model, children's familiarity with numbers (indexed by their counting ability within a particular numeric scale) is a good predictor of shape of the participants' mental number line (e.g., linear or logarithmic). That is, if participants are familiar with the numeric context in which they are asked to make estimates, the best fitting function of participants' number line estimates should be linear with a greater slope than the scale with which they are unfamiliar, thereby leading to a pattern of estimates that appears logarithmic. Within this account, apparent fit of the logarithmic model is illusory, whereas a segmented linear model, consisting of two simple linear regression functions that intersect at a "change point" provides a better model fit. Most impressively, "change point" in this segmented linear model was correlated with children's counting range, suggesting the apparent fit of the logarithmic function may be a by-product of children's familiarity. In this article, we investigate whether the assumptions of the segmented linear model hold in larger numeric scales (e.g., 0–10,000 and 0–100,000).

Issues Examined in Present Studies

The central purpose of the present studies was to examine how broadly children spontaneously apply linear representations on number lines with large numeric anchors (e.g., 1,000, 10,000, and 100,000; Experiment 1) and to determine whether aligning structure of small and large numeric scales will prompt children to generalize linear representations more broadly than they would without such alignment (Experiment 2).

The purpose of Experiment 1 was to determine age differences in underlying representations that children and adults used when making estimates on number lines of increasing numerical magnitude and track the developmental trajectory of participants' linearization of estimates on number lines of increasing magnitudes. To investigate these age differences in numerical representations, we examined second-, third-, and sixth-grade students' number line estimation performance in large numerical contexts (e.g., 0–1,000, 0–10,000, and 0–100,000) prior to children receiving any corrective feedback from the experimenter. These children's results were then compared to the performance of college-aged adults who were asked to complete the same task. From the results of Experiment 1, we also hoped to identify an age group where there was a large potential for generalizing a linear representation of numbers to much larger orders of magnitude. Experiment 1 also allowed us to investigate whether the assumptions of Ebersbach et al.'s (2008) segmented linear model held at larger orders of magnitude (e.g., 0–10,000 and 0–100,000 scales).

In Experiment 2, we attempted to (a) determine how widely children generalized linear representations of numerical magnitudes after they were given feedback on the correctness of their estimates on a smaller scale and (b) determine whether alignment of small and large numeric scales was sufficient to produce generalization to larger numerical contexts. To meet our goals for Experiment 2, we brought number lines for large scales (0–1,000, 0–10,000, and 0–100,000) into progressive alignment with scales that children already represented linearly (0–100). The alignment procedure we used is considered "progressive" in two senses. First, all children's comparisons were supported by increasing perceptual similarity of small (training problems) and large scales (generalization problems) by matching color of units and orders of magnitude. Second, in our progressive alignment and multiple exemplars conditions, children were able to compare 0–100 problems with 0–1,000, 0–10,000, and 0–100,000 problems; in contrast, children in the no alignment condition were not given this opportunity. Finally, to test for representational change, we examined numerical estimates on a 0–1,000 posttest, where children were not given feedback, perceptual support, or the opportunity to compare problems to smaller scales.

Experiment 1: Long-Term Changes in Representations of Large Numerical Magnitudes

In Experiment 1, we investigated long-term changes in children's estimates of large numerical magnitudes (e.g., 940, 9,400, and 94,000) by examining estimates of second graders, third graders, sixth graders, and adults on 0–1,000, 0–10,000, and 0–100,000 number lines. Previously, number line estimation results have shown parallel developmental changes at different ages. Thus, a logarithmic-to-linear shift occurs between kindergarten and second grade on 0–100 number lines (Siegler & Booth, 2004), and between second and fourth grade for estimates on 0–1,000 number lines (Siegler & Opfer, 2003). In this study, we examined whether yet another logarithmic-to-linear shift occurs among children older than second graders on 0–10,000 and 0–100,000 number lines. This issue was important because findings of parallel developmental changes at older ages would suggest that for many years children face the problem of not realizing when to scale up their linear representation and would thereby raise the scientific issue of how they might make that realization.

Method

Participants. Participants were 24 second graders (mean age = 7.9, *SD* = 0.33; 14 girls and 10 boys), 24 third graders (mean age = 9.23, *SD* = 0.36; 11 girls and 13 boys), 24 sixth graders (mean age = 12.06, *SD* = 0.36; 12 girls and 12 boys), and 24 college-aged adults (mean age = 19.96, *SD* = 1.8; 16 women and 8 men). Children were recruited from elementary schools in largely European American, middle-class suburbs surrounding two large metropolitan cities in the United States. Adults were recruited from an introductory psychology course at a large university in the same city. Children participated in return for a small prize (e.g., a sticker), whereas adults received credit toward their introductory psychology course. One female graduate student and one female research assistant served as experimenters.

Design and procedure. Children and adults were given a number line estimation task that consisted of a line flanked by two hatch marks where the left hatch mark was labeled ''0,'' and right hatch mark was labeled with either ''1,000,'' ''10,000,'' or ''100,000'' depending on experimental condition (see Figure 1). Magnitude of overall scale (0–1,000, 0–10,000, and 0–100,000) was a between-subjects variable to guard against order effects. Across all conditions, participants were asked to estimate the position of a third number that appeared above the midpoint of the number line by making a hatch mark through the line. To-be-estimated numbers were chosen to maximize discriminability of logarithmic and linear functions (i.e., by oversampling at the low end of the scale) and to minimize influence of specific knowledge (e.g., 500 is halfway between 0 and 1,000).

Participants were presented with 1 number line estimation problem per page, which ensured that participants were unable to reference their previous estimates. Participants from each age group were randomly assigned to one of three conditions where they completed 10 number line estimation problems, presented in random order and without feedback from the experimenter: (a) in the 0–1,000 condition, participants estimated the magnitudes 20, 50, 80, 110, 150, 250, 490, 610, 730, and 940; (b) in the 0–10,000 condition, participants estimated the magnitudes 200, 500, 800, 1,100, 1,500, 2,500, 4,900, 6,100, 7,300, and 9,400; and (c) in the 0–100,000 condition participants estimated the magnitudes 2,000, 5,000, 8,000, 11,000, 15,000, 25,000, 49,000, 61,000, 73,000, and 94,000.

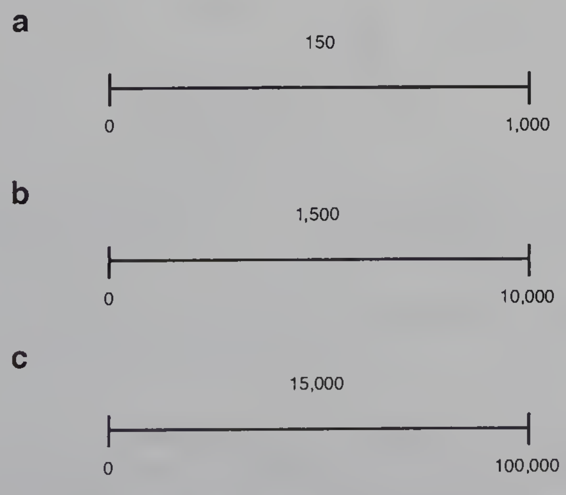

Figure 1. Experiment 1: Illustration of stimuli: (a) 0–1,000 scale, (b) 0–10,000 scale, and (c) 0–100,000 scale.

Results and Discussion

We first examined accuracy of numerical estimates across three experimental conditions. To measure accuracy, we first converted the participant's hatch mark to a numeric value by taking the proportion of the line indicated by the participant (i.e., linear distance from ''0'' mark to participant's hatch mark, divided by total length of line) and then multiplied this proportion by the right numerical anchor (1,000, 10,000, or 100,000). Then, percent absolute error of each participant's error (0%–100%) was calculated by taking the mean absolute difference between each of the participants' estimated values and the actual values divided by the total scale (1,000, 10,000, or 100,000). Finally, accuracy scores were computed by subtracting percent absolute error from 100%.

To analyze long-term changes in estimation accuracy, we conducted a 4 (age group: second graders, third graders, sixth graders, adults) × 3 (scale: 1,000, 10,000, 100,000) analysis of variance (ANOVA) on accuracy scores. As expected, accuracy increased with age, $F(3, 95) = 27.43$, $p < .0001$, $\eta^2 = .74$, and decreased with scale, $F(2, 95) = 7.51$, $p < .001$, $\eta^2 = .13$. These two main effects were also qualified by a significant Age Group × Scale interaction, $F(6, 95) = 2.38$, $p < .05$, $\eta^2 = .13$ (see Table 1). Although third and sixth graders outperformed second graders on 0–1,000 and 0–10,000 number lines, third and sixth graders failed to outperform second graders on 0–100,000 number lines. Thus, age group differences in estimation accuracy depended on numerical context (cf. Siegler & Opfer, 2003), with larger age differences present on 0–1,000 and 0–10,000 number lines than were present on 0–100,000 number lines.

To examine whether age differences in estimation accuracy for 0–10,000 and 0–100,000 number lines were linked to the logarithmic-to-linear shift seen in children's estimates on 0–1,000 number lines (Opfer & Siegler, 2007; Opfer & Thompson, 2008; Siegler & Opfer, 2003; Thompson & Opfer, 2008) and 0–100 number lines (Booth & Siegler, 2006, 2008; Laski & Siegler, 2007; Siegler & Booth, 2004; Siegler & Mu, 2008), we regressed participants' median estimates against the to-be-estimated number, and we compared the fit of the best fitting linear and logarithmic regression functions across the three age groups and scales (see Figure 2). Consistent with previous usage (e.g., Siegler & Opfer, 2003; Thompson & Opfer,

Table 1
Accuracy of Numerical Estimates by Age Group and Condition

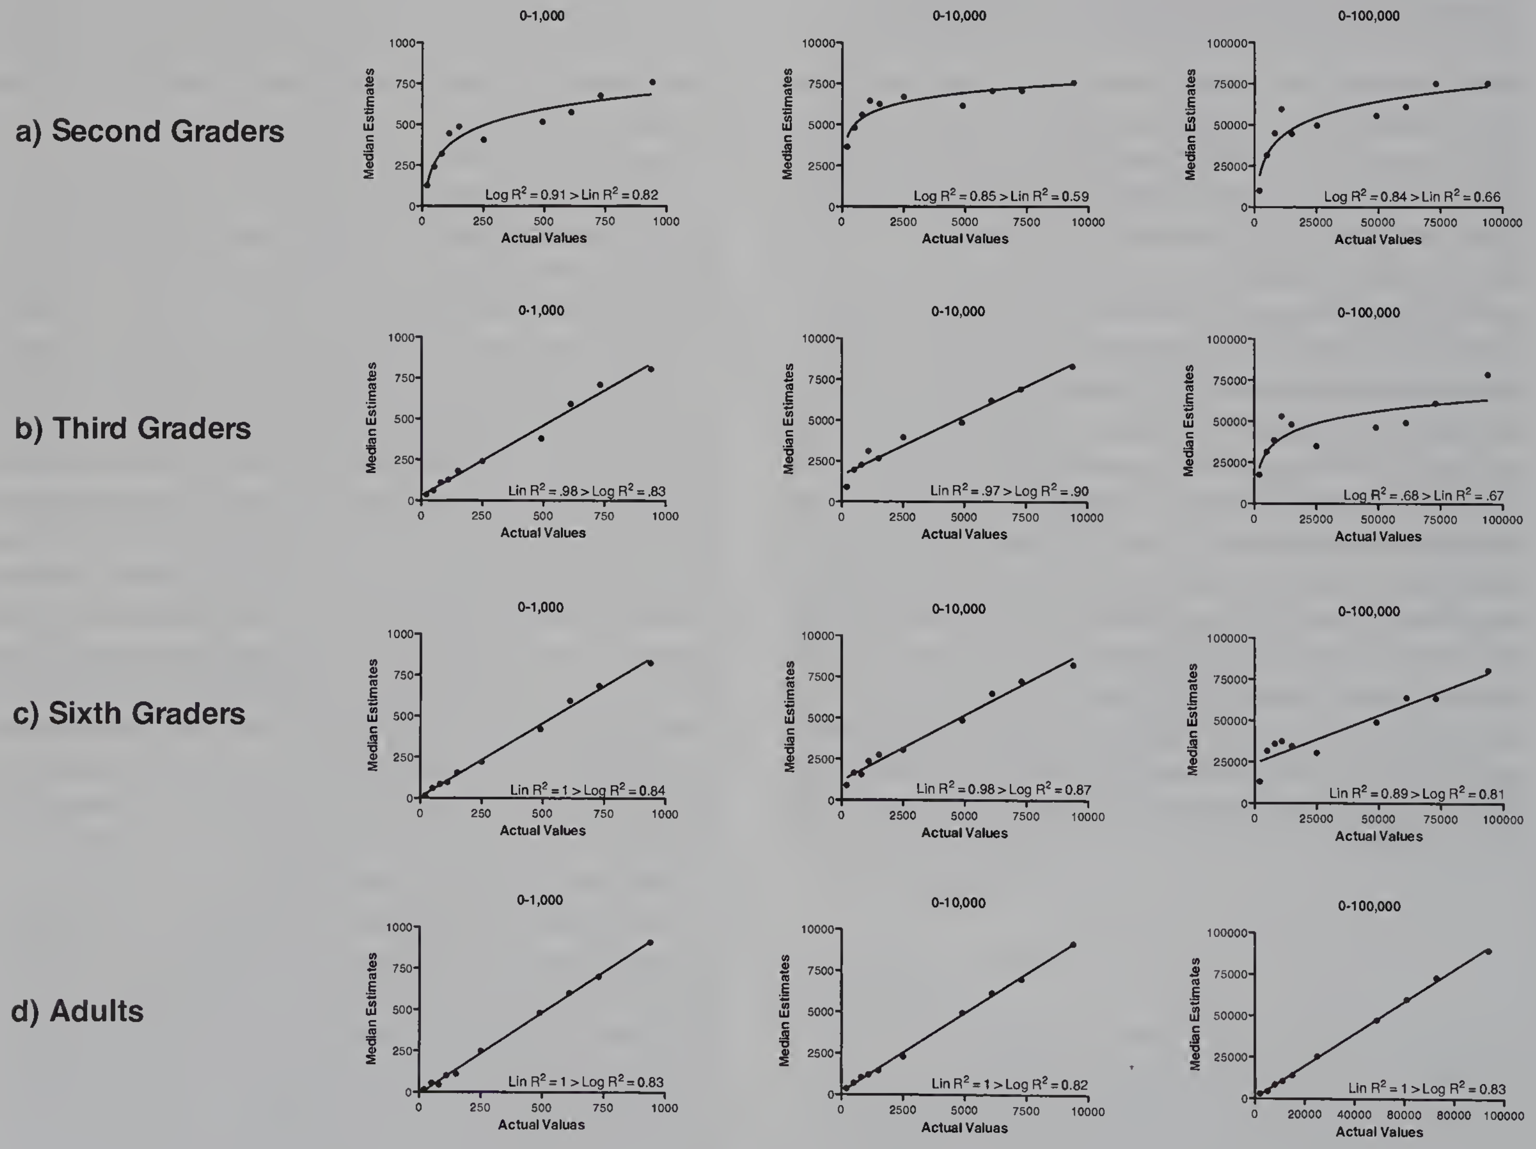

Figure 2. Experiment 1: Median estimates of second graders, third graders, sixth graders, and adults on 0–1,000, 0–10,000, and 0–100,000 number lines.

2008), median estimates were used to minimize the impact of potential outliers at the group level (although similar logarithmic and linear fits were obtained when we used mean estimates in Experiments 1 and 2). Across all three scales, second graders' median estimates were better fit by logarithmic than linear regression functions (0–1,000: logarithmic $R^2 = .91 >$ linear $R^2 = .82$; 0–10,000:

logarithmic $R^2 = .85 >$ linear $R^2 = .59$; 0–100,000: logarithmic $R^2 = .84 >$ linear $R^2 = .66$). Third graders' median estimates, however, were better fit by linear than logarithmic functions on 0–1,000 and 0–10,000 scales (0–1,000: linear $R^2 = .98 >$ logarithmic $R^2 = .83$; 0–10,000: linear $R^2 = .97 >$ logarithmic $R^2 = .90$), but their median estimates on 0–100,000 number lines were better fit by logarithmic than by linear regression functions (0–100,000: logarithmic $R^2 = .68 >$ linear $R^2 = .67$). Finally, median estimates on all three number lines were better fit by linear than by logarithmic regression functions for sixth graders (0–1,000: linear $R^2 = 1 >$ logarithmic $R^2 = .84$; 0–10,000: linear $R^2 = .98 >$ logarithmic $R^2 = .87$; 0–100,000: linear $R^2 = .89 >$ logarithmic $R^2 = .81$) and adults (0–1,000: linear $R^2 = 1 >$ logarithmic $R^2 = .83$; 0–10,000: linear $R^2 = 1 >$ logarithmic $R^2 = .82$; 0–100,000: linear $R^2 = 1 >$ logarithmic $R^2 = .83$).

To determine if the results at the group level held at the individual level, we next regressed each individual participant's estimates against the actual number using logarithmic and linear regression functions, and we used logistic regression to examine the odds of providing linear series of estimates as a function of age (see Figure 3). On 0–1,000 number lines, odds of generating linear estimates tended to increase with age, $\hat{\beta} = .72$, $z = 1.90$, Wald(1, $N = 32$) = 3.60, $p = .058$, indicating that with each year of age children were 2.05 times as likely to generate linear series of estimates. On 0–10,000 number lines, odds of generating linear estimates also increased with age, $\hat{\beta} = .68$, $z = 2.28$, Wald(1, $N = 32$) = 5.2, $p < .05$, indicating that with each year of age children were 1.97 times as likely to generate linear series of estimates. Finally, on 0–100,000 number lines, odds of generating linear estimates increased with age, $\hat{\beta} = .35$, $z = 2.32$, Wald(1, $N = 32$) = 5.4, $p < .05$, indicating that with each year of age children were 1.41 times as likely to generate linear series of estimates.

In summary, estimation accuracy increased with age, with age differences in accuracy being smaller on progressively larger numerical scales. The same pattern was also evident in the proportion of children producing linear series of estimates. Within each numerical scale, generation of linear series of estimates increased with age, but the overall proportion of children generating linear series of estimates again decreased with progressively larger scales. Thus, taken with previous results on numerical estimation in 0–10 and 0–100 contexts, the results of Experiment 1 point to a problem in numerical estimation that is faced to some extent by children from preschool to early adolescence: How to recognize that the linear representation used for small numbers is also appropriate to use for large numbers?

Experiment 2: Effect of Progressive Alignment on Representational Change

In Experiment 2, we investigated the effect of progressive alignment on children's application of linear representations to large numerical scales. Results of Experiment 1 suggested that second graders would serve as ideal participants: Second graders typically represent numbers as increasing linearly on 0–100 number lines and logarithmically on 0–1,000 number lines (Siegler & Booth, 2004; Siegler & Opfer, 2003), thereby making an analogy between the two scales potentially effective in improving representations for larger numbers. To test this idea, we

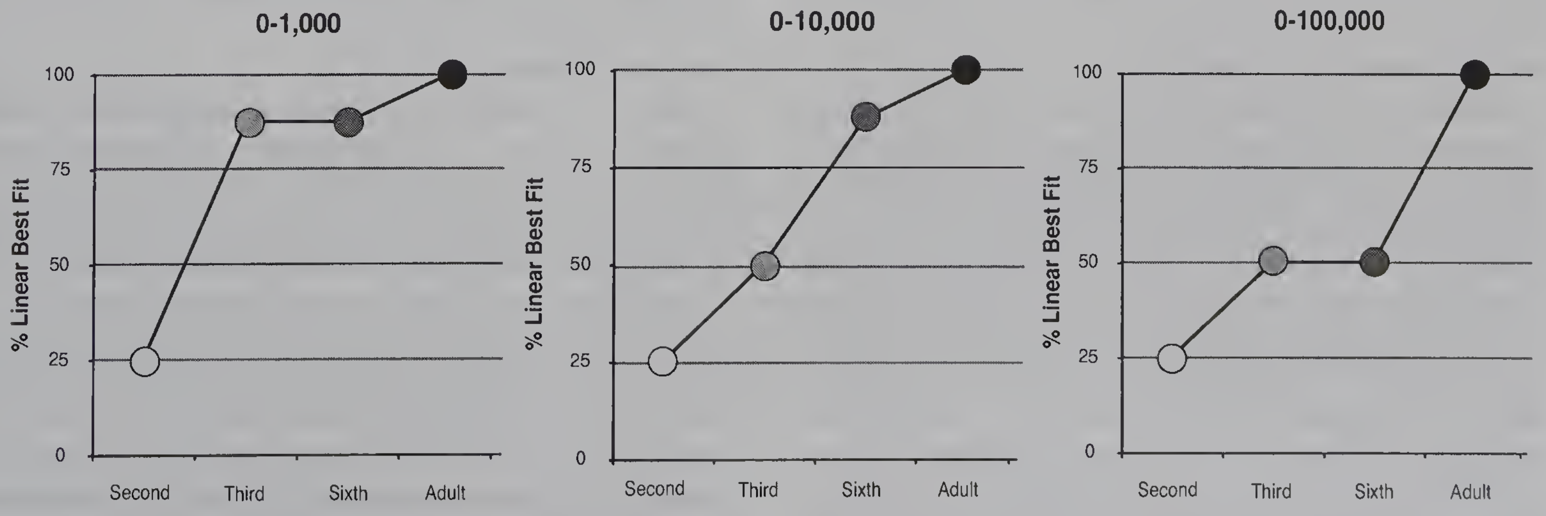

Figure 3. Experiment 1: Percentage of second graders, third graders, sixth graders, and adults who were best fit by the linear regression function on 0–1,000, 0–10,000, and 0–100,000 number lines.

examined effects of three training procedures to elicit linear estimates from second graders on 0–1,000, 0–10,000, and 0–100,000 number lines. In all three procedures, children were given feedback when making estimates on 0–100 number lines. The critical difference between procedures, however, was whether and how 0–100 number lines were aligned with 0–1,000, 0–10,000, and 0–100,000 number lines. Our central hypothesis was that progressive alignment of small and large number lines would lead children to change their estimates of numerical magnitude on large number lines, despite being given no direct feedback that they should do so.

We hypothesized that progressive alignment would promote representational change in the following way. Participants should first make surface-level comparisons across 0–100 training problems and note that a particular numerosity should be placed in the same location on the number line regardless of whether the numerosity is presented in the context of a blank 0–100 number line, a 0–100 pear line, a 0–100 cherry line, or a 0–100 carrot line. Then, we hypothesized that participants should note color of units (e.g., pears, cherries, carrots) corresponding to differing orders of magnitude (0–1,000 with one green zero, 0–10,000 with two red zeros, and 0–100,000 with three orange zeros, respectively), and this should subsequently highlight the underlying decimal system (15 cherries:100 cherries::1,500:10,000).

Method

Participants. Participants were 46 second graders (mean age = 7.78, *SD* = 0.41) recruited from elementary schools in largely European American, middle-class suburbs surrounding two large metropolitan cities in the United States. There were 20 girls and 26 boys that participated in return for a small prize (e.g., a sticker). One female graduate student served as experimenter.

Design and procedure. Children estimated the placement of numbers on number lines across three phases of the experiment: training, generalization, and posttest (see Figure 4). Number lines were flanked by two hatch marks, the left hatch mark was labeled "0," and right hatch mark was labeled "100," "1,000," "10,000," or "100,000." On each trial, children estimated the position of a number (one per number line) by making a hatch mark through the line. To-be-estimated numbers (2, 5, 8, 11, 15, 25, 49, 61, 73, 94, and multiples thereof) were chosen to reduce influence of specific knowledge (e.g., that 50 is half of 100) and to oversample the low end of the scale to maximize discriminability of logarithmic and linear functions.

Figure 4 illustrates training, generalization, and posttest phases for three experimental conditions: no alignment, multiple exemplars, and progressive alignment. During training (Figure 4, left column), all participants received corrective feedback in the 0–100 scale that indicated how close to or far from the actual location of the to-be-estimated number their hatch marks were to ensure children possessed a linear representation in this scale (see Opfer & Siegler, 2007, for a more detailed description of the feedback procedure). We reasoned that if children possessed a linear representation in the 0–100 scale, participants across all experimental groups should be equally likely to bootstrap their linear representation to larger numerical scales (0–1,000, 0–10,000, and 0–100,000).

All training problems specified units (i.e., green pears, red cherries, and orange carrots) and were completed in the following order: blank number line, pear number line, cherry number line, then carrot number line. After children completed these training problems, they were told that their estimates did not differ much over different units (e.g., "It does not matter if you see pears, cherries, carrots, or nothing at all after the number 15, if you see the number 15, you should make your mark right here").

In the generalization phase (Figure 4, middle column), we highlighted similarity of generalization and training problems (that color of units matched color of zeros in right numerical anchor) and told participants to "try some more problems just like the ones you just finished" as the experimenter drew an arrow from the relevant training problem to its related generalization problem. During generalization, participants made estimates in the 0–100, 0–1,000, 0–10,000, and 0–100,000 scales without corrective feedback for the numerosity on which they were just trained.

Figure 4 illustrates training and generalization for the number 15. Participants completed one training problem at a time (e.g., 15 on a 0–100 number line, 15 pears on a 0–100 pear line, 15 cherries on a 0–100 cherry line, and 15 carrots on a 0–100 carrot line), and then completed generalization problems in the 0–100 through 0–100,000 scale (e.g., 15 on a 0–100 number line, 150 on a 0–1,000 number line, 1,500 on a 0–10,000 number line, and 15,000 on a 0–100,000 number line). This training and generalization procedure was repeated with the other nine numerosities we investigated for a total of 40 training trials and 40 generalization trials.

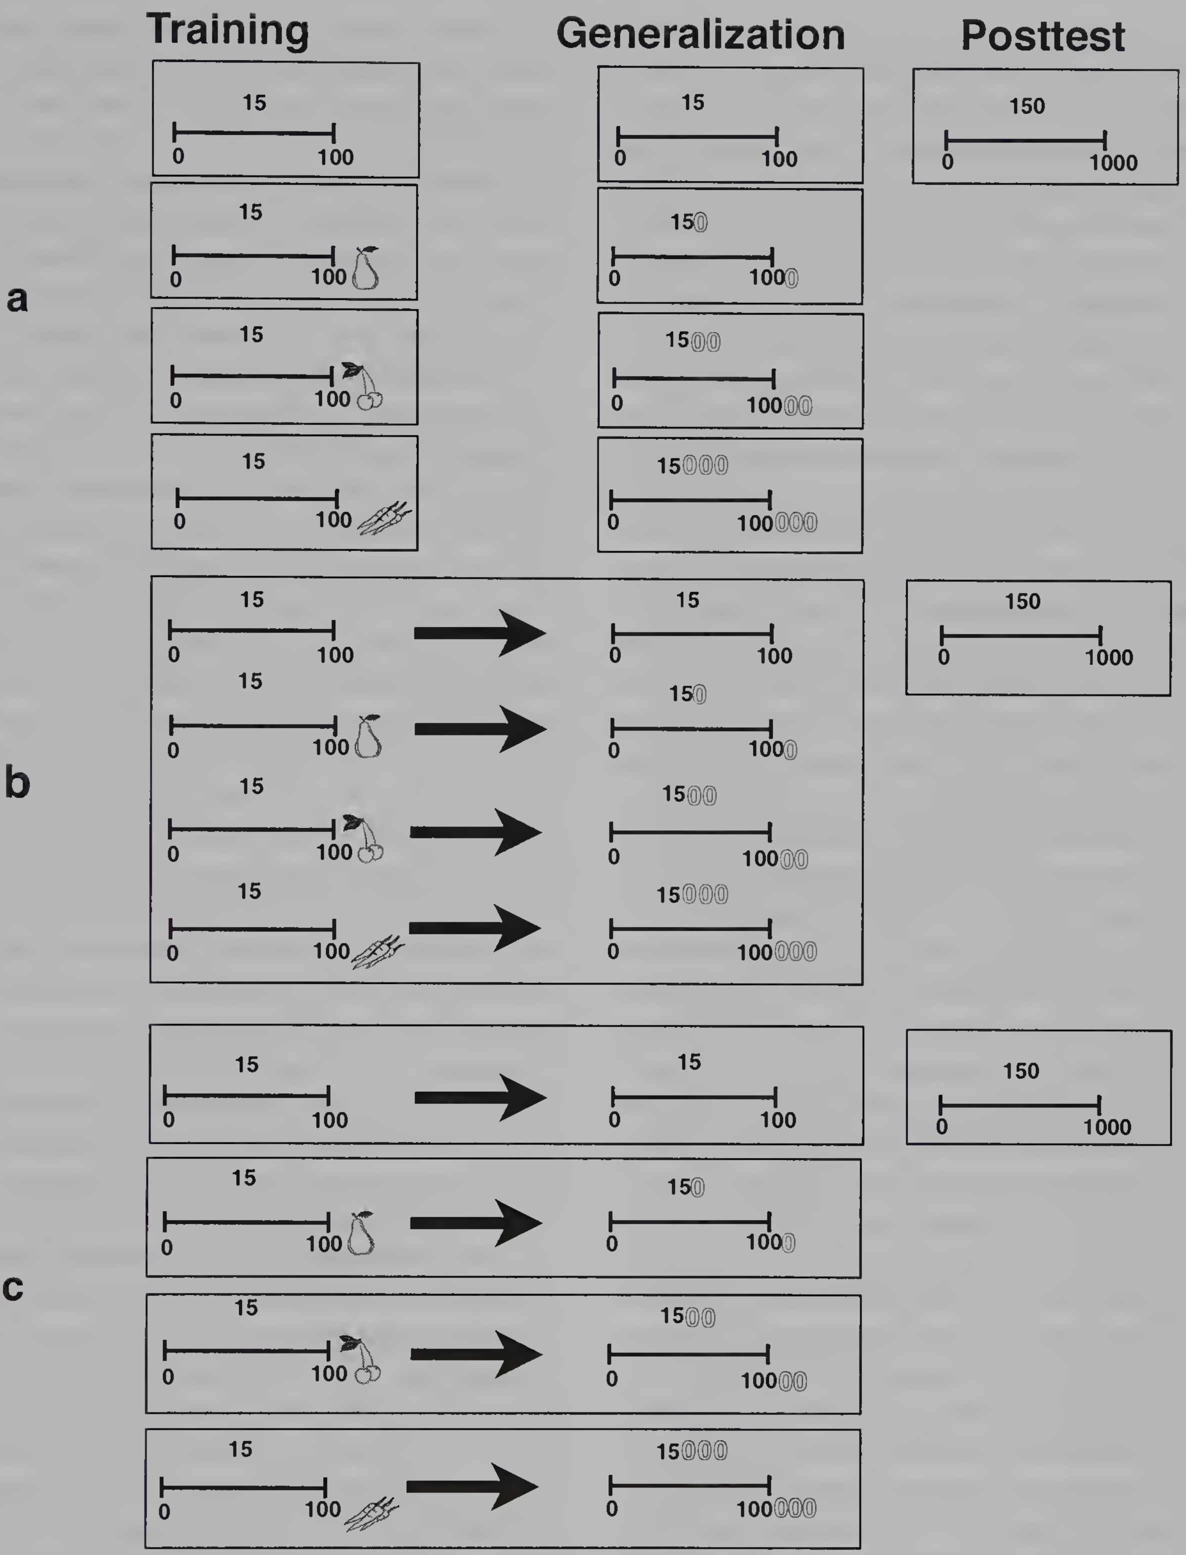

Figure 4. Experiment 2: Illustration of stimuli: (a) no alignment condition, (b) multiple exemplars condition, and (c) progressive alignment condition.

Note. Units in 0–100 training problems (i.e., pears, cherries, and carrots) were colored to correspond to the final 1–3 zeros in 0–1,000, 0–10,000, and 0–100,000 generalization problems (e.g., 3 carrots and the final three zeros in 100,000 were colored orange). Participants in the no alignment condition were presented one training or generalization problem per page, so these participants could not compare across training and generalization problems. Participants in the multiple exemplars condition were presented all training and generalization problems on one page, so these participants could compare training to other training problems, generalization to other generalization problems, or training to generalization problems. Participants in the progressive alignment condition were presented with one training–generalization pair at a time, so these participants could compare across relevant training–generalization pairs only.

Following completion of the training and generalization procedure detailed earlier, participants completed a 10-problem posttest phase (Figure 4, right column). Participants completed the same 10 problems administered for the 0–1,000 generalization phase (e.g., 20, 50, 80, 110, 150, 250, 490, 610, 730, 940). Like the generalization phase, participants did not receive corrective feedback during posttest. Unlike generalization, posttest problems contained no perceptual support (e.g., fruit and vegetable icons and colored zeros).

To test the effect of alignment on transfer from training to generalization and posttest problems, participants were randomly assigned to one of three between-subjects experimental conditions: no alignment, multiple exemplars, and progressive alignment (cf. Figures 4a to 4c). In the no alignment condition, participants received training and generalization problems one at a time; thus, participants were not able to compare problems on which they received feedback during training (e.g., placement of 15 cherries on a 0–100 cherry line) with problems they completed during the generalization phase (e.g., 1,500 on a 0–10,000 number line). In the multiple exemplars and progressive alignment conditions, participants received the same training problems and corrective feedback as in the no alignment condition, but generalization problems were presented alongside previously solved training problems, thereby allowing children in these groups to compare generalization problems to training problems. The multiple exemplars and progressive alignment conditions differed from one another in that participants in the progressive alignment group were *only* able to compare one training–generalization pair at a time, thereby focusing on the critical similarity (e.g., 15 cherries:100 cherries::1,500:10,000). In contrast, participants in the multiple exemplars condition saw *all* training and generalization problems on one page. Participants in the multiple exemplars condition were able to compare training problems to generalization problems just like participants in the progressive alignment condition (and thus draw the relevant analogy), but participants in the multiple exemplars condition were also given the opportunity to make less useful comparisons, such as comparing training problems to training problems (cherries vs. carrots) and comparing generalization problems to generalization problems (10,000 vs. 100,000). To put it another way, participants in the progressive alignment condition were constrained in the types of comparisons they could make, whereas participants in the multiple exemplars condition were unconstrained in the comparisons they could make.

Results and Discussion

In the following sections, we will analyze children's number line estimates during training, generalization, and at posttest to determine whether children were capable of using an analogy to scale up their linear representation from 0–100 number lines to larger numerical magnitude contexts.

Training. We first examined accuracy of numerical estimates during training to confirm that all three experimental groups performed well on 0–100 number lines, which were problems from which the groups were expected to generalize in the generalization and posttest phases. As expected, a 3 (condition: no alignment, multiple exemplars, progressive alignment) × 4 (unit type: none, pear, cherry, carrot) ANOVA revealed no effect of condition or Condition × Unit Type interaction. Presumably due to the fixed order of items, however, there was a small but reliable effect of unit type, $F(3, 129) = 15.13$, $p < .001$, $\eta^2 = .24$, with less accurate estimates for the first type of units presented (none, $M = 89\%$) than for the other three types of units (pear: $M = 94\%$, $d = 0.82$; cherry: $M = 94\%$, $d = 1.21$; carrot: $M = 93\%$, $d = 1.09$; $ps < .01$), which did not differ significantly.

To confirm that these high levels of accuracy were associated with use of linear representations, we again compared the fit of the best fitting linear and logarithmic regression functions to median numerical estimates across three experimental conditions. Across all training problems, participants in the no alignment condition produced more linear than logarithmic series of estimates (blank: linear $R^2 = .99 >$ logarithmic $R^2 = .85$; pear: linear $R^2 = .99 >$ logarithmic $R^2 = .86$; cherry: linear $R^2 = 1 >$ logarithmic $R^2 = .85$; carrot: linear $R^2 = 1 >$ logarithmic $R^2 = .85$), as did participants in the multiple exemplars condition (blank: linear $R^2 = .99 >$ logarithmic $R^2 = .86$; pear: linear $R^2 = 1 >$ logarithmic $R^2 = .84$; cherry: linear $R^2 = 1 >$ logarithmic $R^2 = .84$; carrot: linear $R^2 = 1 >$ logarithmic $R^2 = .84$), and the progressive alignment condition (blank: linear $R^2 = .873 >$ logarithmic $R^2 = .869$; pear: linear $R^2 = 1 >$ logarithmic $R^2 = .84$; cherry: linear $R^2 = 1 >$ logarithmic $R^2 = .83$; carrot: linear $R^2 = 1 >$ logarithmic $R^2 = .83$). A similar pattern also emerged from the examination of individual children's estimates. Regardless of units, most children's estimates were best fit by the linear function in the no alignment condition ($M = 93\%$ best fit by linear), the multiple exemplars condition ($M = 88\%$ best fit by linear), and the progressive alignment condition ($M = 86\%$ best fit by linear). Further, tests of Fisher's exact probabilities revealed no association between experimental group and best fitting regression function (logarithmic versus linear; $ps > .05$).

Thus, all three experimental groups were likely to use an accurate, linear representation of numerical magnitudes in the 0–100 scale, suggesting they were equally likely to benefit from applying their linear representations of the 0–100 scale to 0–1,000, 0–10,000, and 0–100,000 scales. In the next section, we explored whether all three groups did in fact apply their linear representations to larger scales and whether that application was fostered by alignment of small and large numerical scales.

Generalization. To test the effect of progressive alignment on generalization of linear representations to larger scales, we first examined accuracy across three experimental groups. To do this, we conducted a 3 (condition: no alignment, multiple exemplars, progressive alignment) × 4 (scale: 0–100, 0–1,000, 0–10,000, 0–100,000) repeated measures ANOVA on accuracy scores on generalization problems. As expected, there was a main effect of scale, $F(3, 41) = 28.73$, $p < .001$, $\eta^2 = .02$, and a main effect of condition, $F(2, 43) = 10.44$, $p < .001$, $\eta^2 = .91$, although these main effects were qualified by a significant Condition × Scale interaction, $F(6, 84) = 2.99$, $p < .01$, $\eta^2 = .04$.

Further, to investigate significant condition differences in levels of accuracy across generalization problems, we conducted post hoc ANOVAs to determine how differing amounts of alignment (e.g., no alignment, multiple exemplars, progressive alignment) affected accuracy of children's estimates (see Table 2). As anticipated, there were no differences in accuracy across experimental conditions for the 0–100 blank number line problems, presumably because second graders typically represented magnitudes of these numbers as increasing linearly. However, children assigned to the multiple exemplars and progressive alignment conditions produce more accurate series of number line estimates for 0–1,000, 0–10,000, and 0–100,000 generalization problems as compared to those children assigned to the no alignment condition.

To assess whether these changes in accuracy were caused by the logarithmic-to-linear shift, we next compared the fit of the best-fitting linear and logarithmic functions to median numerical estimates across three experimental groups (Figure 5). As in performance on 0–100 problems during training, the best fitting function for all experimental conditions on the 0–100 generalization problems was the linear rather than logarithmic regression function (no alignment, linear $R^2 = 1.0 >$ logarithmic $R^2 = .86$; multiple exemplars, linear $R^2 = .99 >$ logarithmic $R^2 = .85$; progressive alignment, linear $R^2 = .99 >$ logarithmic $R^2 = .85$).

Experimental groups differed, however, for larger generalization problems (0–1,000, 0–10,000, and 0–100,000). For the no alignment group, the best fitting function was logarithmic across the 0–1,000 and 0–10,000 generalization problems (logarithmic $R^2 = .9$ and .85, respectively); on 0–100,000 generalization problems, both the linear ($R^2 = .46$) and logarithmic function ($R^2 = .39$) provided uncommonly poor fits to children's estimates. For the multiple exemplars group, the best fitting function was the linear one for both 0–1,000 and 0–10,000 generalization problems (linear $R^2 = .96$ and .84, respectively), but the logarithmic function was the best fitting function across 0–100,000 generalization problems (logarithmic $R^2 = .86$). Finally, for the progressive alignment group, the linear function provided the best fit across 0–1,000, 0–10,000, and 0–100,000 generalization problems (linear $R^2 = 1.00$, .98, and .98, respectively).

To ensure that these condition differences in model fit were due to the effect of alignment and not due to irregularities arising from averaging, we used Fisher exact probability tests to examine reliability of association between condition and percentage of individual children best fit by the linear function. On the two smaller scales, 0–100 and 0–1,000, we observed no significant associations between condition and fit by the linear function (on

Table 2
Accuracy of Numerical Estimates by Scale and Condition

	0–1,000	0–10,000	0–100,000
Condition	$F(2, 45) = 8.38$, $p < .001$ Progressive, $M = 90\% >$ No, $M = 78\%$, $d = 1.25$ Multiple exemplars, $M = 89\% >$ No, $M = 78\%$, $d = 1.09$	$F(2, 45) = 6.06$, $p < .01$ Progressive, $M = 83\% >$ No, $M = 63\%$, $d = 0.95$ Multiple exemplars, $M = 84\% >$ No, $M = 63\%$, $d = 1.16$	$F(2, 45) = 10.89$, $p < .001$ Progressive, $M = 85\% >$ No, $M = 63\%$, $d = 1.48$ Multiple exemplars, $M = 82\% >$ No, $M = 63\%$, $d = 1.43$

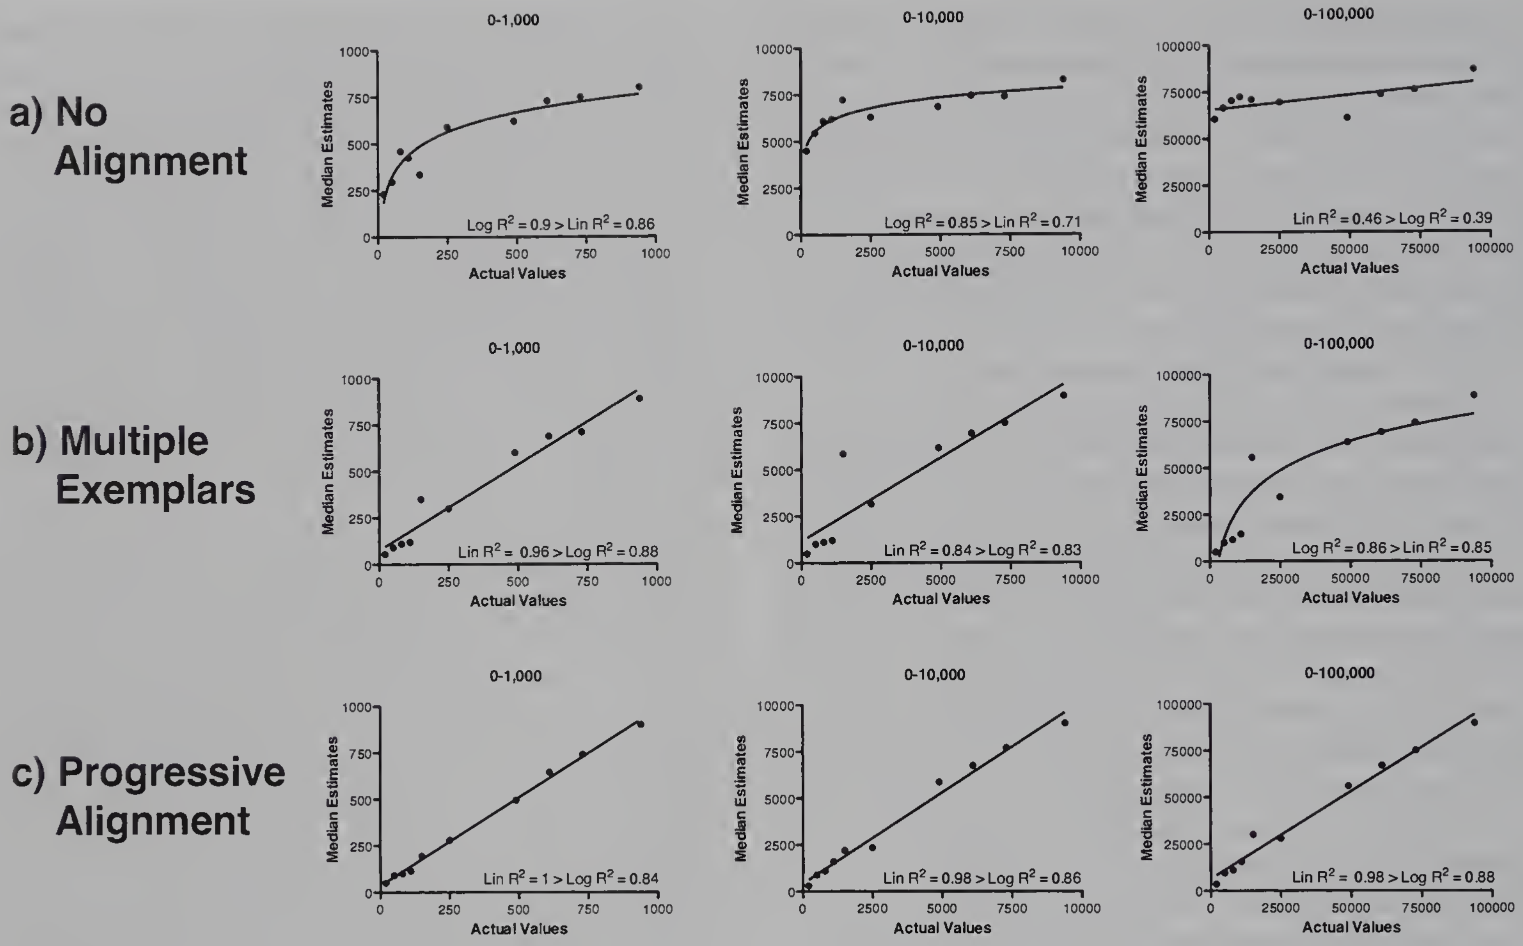

Figure 5. Experiment 2 (generalization): Median estimates of participants in the no alignment, multiple exemplars, and progressive alignment groups on 0–1,000, 0–10,000, and 0–100,000 number lines.

0–100 scales: no alignment, 93%; multiple exemplars, 100%; progressive alignment, 100%; on 0–1,000 scales: no alignment, 57%; multiple exemplars, 69%; progressive alignment, 81%). On the two larger scales, 0–10,000 and 0–100,000, however, we observed significant associations between condition and fit by the linear function, with the progressive alignment group outperforming the other two experimental groups (on 0–10,000 scales: no alignment, 50%; multiple exemplars, 56%; progressive alignment, 100%; on 0–100,000 scales: no alignment, 50%; multiple exemplars, 50%; progressive alignment, 100%; *ps* < .05; compare to results of Experiment, 1 illustrated in Figure 3). Thus, while children generalized linear representations of numerical magnitude to 0–1,000 scales with and without the help of alignment of small and large numerical scales, children's generalization of linear representations to 0–10,000 and 0–100,000 scales only occurred when these scales were individually aligned with 0–100 scales, as they were for children in the progressive alignment group.

In summary, findings from the generalization phase of Experiment 2—greater estimation accuracy on number lines with larger numeric values, better fits of the linear regression function to estimates on number lines with larger numeric values, and strong associations between alignment and likelihood of providing linear estimates on number lines with larger numeric values—indicate that progressive alignment of large and small number lines led children to scale up their linear representations of numerical magnitude more so than no alignment of large and small scales (no alignment condition) or alignment of units as well as alignment of large and small scales (multiple exemplars condition).

We speculate the reason children did not scale up their linear representation in the multiple exemplars condition, which presumably offered a wealth of alignment possibilities, may have resulted from learners failing to align the most effective pairs (e.g., 0–100 pears training problem compared to 0–1,000 generalization problem with one green zero). That is, in the multiple exemplars condition, children were not constrained in the types of comparisons they made across problem types because they saw all problems on one page. When faced with the ability to compare any of the number lines on the page, learners may have failed to notice surface similarities across their initial comparisons.

If the children failed to see how the problems encompassing small and large numeric scales related to one another, they may have given up on their attempts to find commonalities. Alternatively, children may have used a more shallow comparison process by simply scanning the multiple exemplars for obvious, surface commonalities as compared to engaging in a deeper comparison process that might highlight structural similarities (e.g., decimal system) across the small and large numerical scales. In the next section, we examined whether advantages of progressive alignment over other training procedures persisted to a posttest, where alignment of large and small scales desisted.

Posttest. To determine whether participants had transferred their linear representation of number to larger numbers generally or just to number lines with perceptual support (e.g., fruit and vegetable icons and colored zeros), we examined performance on a blank 0–1,000 number line that was unaccompanied by previously solved problems and without units and zeroes sharing a common color. Our reasoning was that if children had grasped the analogy we intended, they would distance their hatch marks as a linear function of actual value on number lines identical to those used in previous studies (i.e., without perceptual support).

As illustrated in Figure 6, estimates of participants in the progressive alignment group were indeed better fit by the linear function ($R^2 = .95$) than by the logarithmic ($R^2 = .76$). In contrast, children's estimates in the no alignment group were better fit by the logarithmic function ($R^2 = .91$) than by the linear ($R^2 = .66$), and children's estimates in the multiple exemplars group were also better fit by the logarithmic function ($R^2 = .83$) than by the linear ($R^2 = .58$). Finally, the same advantage of the progressive alignment group was evident in the percentage of children best fit by the linear as opposed to the logarithmic function (compare with 0–1,000 condition in Figure 3), with 63% of children in the progressive alignment group generating linear series of estimates versus 29% of children in the no alignment group, $\chi^2(1) = 3.45$, $p = .06$, and 25% of children in the multiple exemplars group, $\chi^2(1) = 4.57$, $p < .05$.

General Discussion

The ability to carry out effortless structural alignment is a hallmark of human cognitive processing (Gentner & Markman, 1997; although see Kurtz et al., 2001, for an instance of more effortful alignment) and a potentially general mechanism of cognitive change (Chen & Klahr, 1999; Gentner et al., 2001; Holyoak & Thagard, 1995; Opfer & Siegler, 2004). In our study, we investigated whether structural alignment of small numerical scales and large numerical scales might lead to a representational change in the domain of number (logarithmic-to-linear shift) that has been observed across a large number of age groups (Siegler & Booth, 2004; Opfer & Thompson, 2008; Siegler & Opfer, 2003).

Our first experiment illustrated large numeric contexts in which second-, third-, and sixth-grade children produced linear versus logarithmic series of numerical magnitude estimates. Our results supported the idea that abandoning logarithmic representations of numerical magnitude is not an all-or-none process. Rather, extending linear representations of number to ever-larger numeric scales occurs gradually over time, with half or more of each group of children continuing to use logarithmic representations on one or more tasks (e.g., 50% of sixth graders on 0–100,000; 50% of third graders on 0–10,000 and 0–100,000; and 75% of second graders on 0–1,000, 0–10,000, and 0–100,000). Thus, for large numeric scales, children's use of logarithmic representations appeared unchanged by their experiences—either due to the low frequency with which they are likely to receive any information

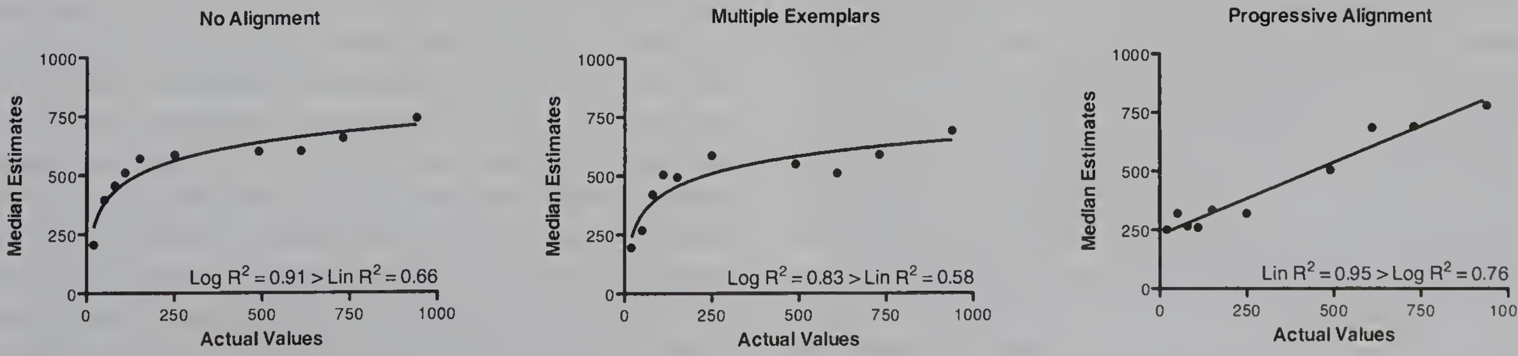

Figure 6. Experiment 2 (posttest): Median estimates of participants in the no alignment, multiple exemplars, and progressive alignment groups on unsupported 0–1,000 number lines.

about values in these large scales or due to an age-related conceptual limitation in representing large numeric values.

Our second experiment indicated that failure to abandon logarithmic representations of large numbers in favor of linear ones is likely due to poverty of input regarding large numerical values. Thus, when second graders—who produced logarithmic estimates at the highest rates (75%) across all three tasks in Experiment 1—were simply provided with the opportunity to align number line problems for small numerical scales (0–100) with number line problems of larger numerical scales (0–1,000, 0–10,000, and 0–100,000), children abandoned use of the logarithmic representation with surprising frequency. This representational change was most robust in the progressive alignment condition, where children could directly compare only relevant training and generalization problems and where 0% of children provided estimates better fit by the logarithmic than linear functions on 0–10,000 and 0–100,000 problems. Moreover, these children continued to generate linear estimates on posttest, which children in the multiple exemplars and no alignment conditions did with much less consistency. Progressive alignment of small and large numerical scales focused children's attention on the most informative surface level comparisons allowing children to search for deeper, structural commonalities as well. Children in the multiple exemplars condition were not at all constrained when attempting to compare small and large numerical scales. It is likely that surface dissimilarities (e.g., pears, cherries, carrots, 0–100, 0–1,000, 0–10,000, 0–100,000) confused learners in the multiple exemplars condition and prohibited these learners from discovering deeper, structural similarities across number lines of small and large numerical scales.

Analogy as a Mechanism of Representational Change

Why did alignment of small and large numeric scales produce rapid changes in numerical estimation and generalization of the linear representation? In our experiment, we aligned contexts in which children were familiar (e.g., 0–100) with larger, less familiar numeric contexts (e.g., 0–1,000 to 0–100,000). This alignment methodology apparently prompted second graders to scale up their linear representation of numbers by highlighting the underlying structure of the decimal system and thereby bootstrap the linear representation they already possessed in a familiar numeric context (0–100) to less familiar numeric contexts (0–1,000 through 0–100,000). Although this mechanism of representational change had been suggested in an earlier microgenetic study of numerical estimation (Opfer & Siegler, 2007), the present work provided unusually strong support for the idea by showing both that the representational change can occur without any feedback as well as by showing that the learning can be generalized very far outside the training space.

These findings on the effect of alignment in producing analogies are also apparent in a number of other empirical studies (Dixon & Dohn, 2003; Gentner, Loewenstein, & Thompson, 2003; Kotovsky & Gentner, 1996; Uttal, Schreiber, & DeLoache, 1995), where alignment has led people to compare examples and thereby extract an abstract relational schema that might be applied to other relevant problems. For example, novice negotiators who were learning about negotiation strategies were asked to compare written case studies in the hopes that a common negotiation strategy would be extracted despite differing surface features of presented problems. Novice negotiators who compared two written case studies detailing negotiation strategies were better able to abstract general problem-solving schemas which they later applied to future negotiation situations, like face-to-face negotiations, than were negotiators who were not explicitly told to compare cases or who received no case-based training whatsoever (Gentner et al., 2003; Loewenstein, Thompson, & Gentner, 2003). The general problem-solving schema was abstracted, or disembedded, from the original learning context so that it could be applied to other relevant case studies outside the original learning context.

Likewise, other investigators have similarly noted that alignment specifically and similarity comparison in general allows participants to disembed underlying structural relations in problem-solving tasks. In classic scale model problem-solving tasks conducted by DeLoache and her colleagues (e.g., DeLoache, Kolstad, & Anderson, 1991; Uttal et al., 1995), young children were shown where a hidden object could be found in a scale model and then were asked to locate the hidden object in the larger artificial room the model represented. Not only must children realize the scale model is related to the larger room and therefore locations in the model can be mapped directly onto this larger artificial room in a one-to-one fashion, but children must also hold in mind the representation of the scale model to find the hiding place of the object in the larger room (Uttal et al., 1995). According to DeLoache et al. (1991), one way that children successfully uncover the one-to-one mapping between the model and artificial room is by attending to overlapping similarity in the two spaces (e.g., object matches and size or scale of rooms). Further, Loewenstein and Gentner (2001) found that 3-year-olds' search behavior in the DeLoache hiding task was improved by their ability to compare two sequential hiding tasks transpiring across two highly similar hiding rooms whereas search behavior was not improved for those 3-year-olds who saw the highly similar hiding rooms but were not prompted to compare them.

Another example of participants' ability to abstract a general problem-solving schema through alignment is Dixon and Dohn's (2003) alternating sequence problems. In these problems, participants were shown a connected sequence of balance scales or gears and then were asked to predict the position of the last balance scale in sequence (up or down) or direction of movement of the last gear in sequence (clockwise or counterclockwise). Participants who discovered the underlying structural relation through comparison of multiple examples of alternating sequence problems often extracted the solution more quickly or readily and more consistently transferred the solution to new problem types than did those participants who were explicitly instructed on the relation uniting the problems (e.g., alternating sequences: up, down, up, down or clockwise, counterclockwise, clockwise, counterclockwise).

As in these cases of learning, children in our own experiments were given opportunities that seemed crucial for eliciting their analogies. First, they were given opportunity to compare across multiple training problems, much like novice negotiators comparing written case studies (Gentner et al., 2003), toddlers comparing scale models to larger rooms (DeLoache et al., 1991; Loewenstein & Gentner, 2001), adults comparing alternating sequence problems (Dixon & Dohn, 2003), and children comparing geometric shapes that differed in symmetry and monotonicity in match to sample tasks (Kotovsky & Gentner, 1996). Second, our participants were given perceptual matches to facilitate alignment of small number line problems (e.g., two red cherries in 0–100 problems) with large number line problems (e.g., two red zeros in 0–10,000 problems), just as DeLoache and colleagues' toddlers used high physical similarity across the size of the scale model and artificial room. Third, not only did presence of overlapping similarity lead participants to abstract structural relations, but children's superior understanding of the 0–100 scale was probably crucial, given the finding that increasing participants' knowledge base increases the likelihood of learners noticing structural relations (Kotovsky & Gentner, 1996). Thus, Experiment 2 appeared to provide many critical opportunities that children needed to draw analogies from more familiar to less familiar problems.

Alternative Role for Familiarity in Numerical Estimation: Segmented Linear Model

According to the segmented linear model, children's familiarity with numbers, as indexed by counting ability within a particular numeric scale, is a good predictor of whether children produce linear estimates (as in familiar numeric scales) or logarithmic estimates (as in unfamiliar numeric scales). Although, according to Ebersbach et al. (2008), the fit of the logarithmic function may be illusory, and children's estimates might be better fit by two linear regression functions that intersect at a "change point."

Results of Experiment 1 provided an unusual opportunity to evaluate this alternative model, and our results do not support the segmented linear model. Specifically, when we fit estimates using the segmented linear function, we found increasingly larger change points as numeric context increased from 0–1,000 (second grade: 158.7, third grade: 366.5, sixth grade: 386.3, adults: 421.35), 0–10,000 (second grade: 2,330, third grade: 2,500, sixth grade: 4,263, adults: 3,668), and 0–100,000 (second grade: 37,000, third grade: 26,592.5, sixth grade: 23,798, adults: 48,999.5), $r = .94$, $F(1, 11) = 70.89$, $p < .001$, suggesting that change point is a task-specific scaling parameter for a logarithmic function rather than an index of children's numeric familiarity. To test the idea that change point is just a task-specific scaling parameter, we next regressed mean age of each participant group (second grade: 7.9 years, third grade: 9.23 years, sixth grade: 12.06 years, adults: 19.96 years) against the segmented linear model's change point, and we found no correlation between age and supposed range of children's familiarity, $r = .15$, $F(1, 11) = .23$, $p > .05$, *ns*. Thus, although numeric anchor (0–1,000, 0–10,000, or 0–100,000) accounted for 94% of variation in change points, age, in comparison, accounted for an insignificant (15%) amount of variation in change points.

Although change point of the segmented linear model has been interpreted by Ebersbach et al. (2008) as reflecting a division in children's familiarity with numbers, the finding that change point varied directly with scale of the number line task (0–1,000 through 0–100,000) suggests that change point is better understood merely as a task-specific scaling parameter. This point is clearest for third graders, where data from both Ebersbach et al. (2008) and our own data indicate a change point of approximately 342 and 366 (respectively) on the 0–1,000 task. Taken alone, it is tempting to view 342–366 as an outer range where children's familiarity with numbers might end. However, since we found the same age group of children producing estimates with a change point of 2,500 and 26,592 on a 0–10,000 and 0–100,000 task (respectively) these findings clearly undercut this logic: Change point in a segmented linear model cannot simply index children's numeric familiarity. The alternative explanation—that participants' familiarity with numbers corresponds directly to the task to which they were randomly assigned—is clearly implausible. Thus, although participants in our studies appeared to use their knowledge of a familiar numeric scale (0–100) to draw an analogy to less-familiar scales (0–1,000 through 0–100,000), familiarity itself does not appear to provide a viable alternative explanation for the logarithmic pattern of estimates observed in Experiment 1.

Educational Implications

Understanding of place value, or interrelations of the numeric decimal system, is a part of children's blossoming number sense (U.S. Department of Education, 2008). This number sense, according to a recent report by the National Mathematics Advisory Panel "includes the ability to estimate results of computations and thereby to estimate orders of magnitude" (p. 18). The panel detailed the state of mathematics research and education in the United States and noted the importance of fostering children's number sense because "poor number sense interferes with learning algorithms and number facts and prevents use of strategies to verify if solutions to problems are reasonable" (p. 27).

Our current research on alignment of small and large numerical scales offers a possible means of providing students explicit as well as implicit instruction on place value and the decimal system. In Experiment 2, we showed that progressive alignment of small and large numerical scales leads young children to adopt a linear representation of number and abandon a logarithmic one, which lends support to important educational implications of our results. The educational implication of this alignment methodology is that it might be used as a simple classroom intervention that may allow children to being thinking about numbers in a more adult-like, linear fashion months and maybe even years before classical classroom instruction or life experiences would lead them to do so. As part of the simple intervention, teachers might align small numeric scales with larger ones and even provide a verbal or visual hint about how the decimal system works (e.g., crossing out the extra zero in 0–1,000 order of magnitude to show how it is similar to the 0–100 order of magnitude). To our knowledge, highlighting properties of the decimal system through alignment is not a technique commonly used by elementary school teachers, but based on previous evidence of causal and correlational links between numerical estimation and other mathematical skills (Booth & Siegler, 2006, 2008), we believe this intervention is likely to be an easy and effective one to implement.

Differing Levels of Gender Salience in Preschool Classrooms: Effects on Children's Gender Attitudes and Intergroup Bias

Lacey J. Hilliard and Lynn S. Liben
The Pennsylvania State University

Developmental intergroup theory posits that when environments make social-group membership salient, children will be particularly likely to apply categorization processes to social groups, thereby increasing stereotypes and prejudices. To test the predicted impact of environmental gender salience, 3- to 5-year-old children ($N = 57$) completed gender attitude, intergroup bias, and personal preference measures at the beginning and end of a 2-week period during which teachers either did or did not make gender salient. Observations of peer play were also made at both times. After 2 weeks, children in the high- (but not low-) salience condition showed significantly increased gender stereotypes, less positive ratings of other-sex peers, and decreased play with other-sex peers. Children's own activity and occupational preferences, however, remained unaffected.

People vary along many dimensions such as age, race, political party, hair color, and favorite activities. Why do children use some dimensions rather than others to categorize people into social groups? And what (if any) consequences result from sorting people into those groups? These questions are at the center of a recent formulation of developmental intergroup theory (Bigler & Liben, 2006, 2007) that builds on several other intergroup approaches (Aboud, 2003; Cameron, Alvarez, Ruble, & Fuligni, 2001; Killen & McKown, 2005; Nesdale, 2004; Rutland, 1999; Rutland, Cameron, Milne, & McGeorge, 2005).

Developmental intergroup theory views the emergence of social stereotypes in children through constructivist lenses. Thus, as in other constructivist views of gender development (e.g., gender schema theory; see Martin & Halverson, 1981), children are thought to be active agents in processing social stimuli. Much early research in the constructivist tradition addressed how gender schemata influence the way that children process material differently depending on whether the material is gender traditional versus nontraditional and on whether it is culturally linked to the child's own versus the other sex. Illustrative of the former is research showing that children tend to have difficulty in remembering nontraditional material either by distorting it so that it becomes consistent with gender stereotypes or by forgetting it entirely (e.g., Koblinsky, Cruse, & Sugawara, 1978; Liben & Signorella, 1980). Illustrative of the latter is research showing that children are more likely to attend to, remember, and enact material associated with their own sex (e.g., Grusec & Brinker, 1972; Martin, Eisenbud, & Rose, 1995; Signorella, Bigler, & Liben, 1997). In developmental intergroup theory, these constructive processes are examined for their role in forming and maintaining social-group categories that in turn become the basis for developing stereotypes and prejudices.

Bigler and Liben (2006, 2007) argued that the development and application of children's stereotyping and prejudice are influenced by the salience of groups within children's surroundings. They identified various factors that render groups more or less salient. One factor concerns the degree to

---

The data reported here were collected as part of the first author's master's thesis, conducted under the supervision of the second author. Portions of this work were presented in April 2008 at the Gender Development conference, San Francisco. We express our appreciation to the child-care directors, Janie Hilliard and Barbara Crosby, for their willingness to accommodate this project, and to the participating staff, teachers, children, and parents for their friendly cooperation. We are also grateful to the members of the Cognitive and Social Development Lab at Penn State for their many contributions to data coding and entry, to Rebecca Bigler for her insights during various phases of this research, and to the Faris endowment of Penn State's Department of Psychology for financial support.

Correspondence concerning this article should be addressed to Lacey J. Hilliard or Lynn S. Liben, Department of Psychology, Moore Building, The Pennsylvania State University, University Park, PA 16802. Electronic mail may be sent to hilliard@psu.edu or liben@psu.edu.

which group membership is visually or perceptually observable (e.g., skin color vs. political affiliation). Irrespective of its initial visibility, a particular quality may be made more visible by an environment that marks group membership in some way. For example, men and women may wear different clothing and hair styles that exaggerate their physical differences, members of different religious groups may wear different head coverings or religious symbols, and members of different political parties may don distinctive lapel buttons. In addition, groups may be made more salient through the use of different language and labels to refer to group members (Bigler, Jones, & Lobliner, 1997).

Also contributing to the impact of group divisions is the child's own drive to categorize: As a part of their constructive, self-motivated drive to understand their interactions with their social and physical environment, children attempt to categorize their early environment and then make sense of these categorizations (Waxman & Gelman, 1986; Waxman & Markow, 1998). Thus, when children recognize differences between groups and are made aware of those groups through implicit and explicit categorization and labeling, they are likely to use those bases to divide people into groups. They are then internally and externally driven to attach meaning to those categories. For example, if religion is made salient in a child's environment (e.g., via differential clothing and labeling), young children would be expected to be more vigilant than they otherwise might be in seeking to find what is associated with religion. Children may also treat categories as innate due to their tendency toward essentialism (Gelman, 2003). Thus, if the child's environment divides people by race, children would be expected to be more likely to infer that differences between races rest on fundamental differences between the groups.

Children also have a propensity toward an in-group and out-group bias (Abrams, Rutland, & Cameron, 2003; Killen, Margie, & Sinno, 2006), and thus once children have enacted their categorization processes, they tend to view their own group as superior and the "other" group as inferior. Intergroup approaches have been used to study and understand stereotypes and prejudices in children. Early work showed that once children are assigned to groups, they make positive attributions to their own in-group and negative attributions toward the out-group (Sherif, Harvey, White, Hood, & Sherif, 1961). Consistent with the core tenets of developmental intergroup theory, these intergroup processes are heightened when there is a physical difference between groups (e.g., race; see Aboud, 1988). The importance of the distinction between in- and out-group attitudes has received recent attention, specifically in a call for measures that do not assume a reciprocal association between the two (Brewer, 1999). Recent investigators have also questioned the yoked nature of in-group preference and out-group derogation and have suggested that the two constructs are not inextricably linked (Aboud, 2003; Cameron et al., 2001; Kowalski, 2003).

One important arena in which the processes identified in developmental intergroup theory may operate is gender. Indeed, over a quarter century ago, Bem (1983) offered an analysis that is consistent with the ideas presented in developmental intergroup theory in that she argued that society's emphasis on gender categorization led to a host of dysfunctional and unnecessary sex differences. Despite this critique, children continue to encounter experiences that increase the salience of gender as when teachers greet their pupils with "Good morning, boys and girls" or when schools require that boys and girls wear different-colored robes at commencement ceremonies.

There has been only a small body of empirical research bearing on the impact of different levels of gender salience. Studies have shown the effect of gender labels on attributing traits to individuals (see Stern & Karraker, 1989), but few experiments have evaluated the role of using gendered language in the environment or have studied whether in-group preferences and out-group biases emerge as predicted by intergroup theories. In one of the few relevant studies, Bigler (1995) found that when teachers used gender to organize their elementary school classes, children showed greater gender stereotyping than did children in classrooms that avoided the functional use of gender. In this study, younger children with less advanced classification skills were more susceptible to the effects of the manipulation than older children (i.e., children with less advanced classification skills developed more negative attitudes than peers with more advanced classification skills).

Although not applied specifically to gender, Patterson and Bigler (2006) have provided evidence that even younger children are also susceptible to developing in-group biases based on group divisions. Specifically, they used a novel group paradigm in which preschool children were randomly assigned to different-colored shirts. They found that when the teacher made functional use of color groups (e.g., lining children up for recess by shirt color), children developed significantly stronger in-group biases. However, it remains unknown if preschool children would be affected by gender labeling and organization in classroom environments. Research to address this issue is important not only because of the practical implications for preschool classroom structure but also because it concerns a category division—gender—that is already emphasized heavily in young children's lives. It is possible that in this larger societal context, preschool classroom manipulations would have little impact.

The evidence just discussed suggests that young children's gender attitudes are susceptible to environmental manipulations that make social-group categories highly salient. Research in the intergroup literature has largely focused on the consequences of sorting people into groups and how one's sense of identity toward a group influences intergroup relations (Tajfel & Turner, 1986). Investigators have shown that gender is prevalent as an in-group category and have reported children's gendered play patterns and own-sex preferences (Maccoby & Jacklin, 1987; Yee & Brown, 1992, 1994). Developmental intergroup theory draws on the fields of intergroup relations but provides a model to test *how* stereotypes are formed and exaggerated, specifically by manipulating the salience of a social-group category in children's environments. The current study expands on previous work of intergroup processes and novel group paradigms by incorporating a wide range of measures to assess children's intergroup preferences and peer play behavior in the domain of gender. More specifically, the purpose of the present study was to test whether increasing the salience of gender in preschool classrooms would lead children to develop more highly gender-stereotyped attitudes and whether there would be evidence of both increased in-group and out-group bias (i.e., favoring one's own gender group and avoiding the other-gender group).

To address these questions, children were studied over a 2-week period under one of two gender-salience conditions. In the low-salience condition, children continued to experience a preschool environment in which the teacher avoided making gender explicit. In the high-salience condition, children experienced a preschool environment in which the teacher highlighted gender by using gender-specific language (labeling groups and individuals with gender terms) and by using gender-based organization in the classroom (e.g., assigning boys and girls to separate bulletin boards, lining up boys and girls separately for recess). Based on developmental intergroup theory, we predicted that children in the low-salience condition would show no discernible changes in their gender stereotypes over the 2-week period of the study, whereas children in the high-salience group would show a significant increase in their gender stereotypes (i.e., a decrease in gender flexibility).

If the increased salience of gender in the classroom was indeed found to strengthen children's gender stereotypes, developmental intergroup theory would predict that the high-salience condition should also yield stronger in-group and out-group bias. To test this latter prediction, we assessed children's interest in playing with peers of their own sex (in-group) and with peers of the other sex (out-group). Specifically, both prior to and following the classroom intervention, children were asked to rate their interest in playing with each of the other children in their class, and their average ratings for own- versus other-sex peers were compared across the two times. As an additional posttest measure, children were asked to select which of three groups of unfamiliar peers they would like to play with—one with only boys, one with only girls, or one with both boys and girls. Of interest was whether children in the high-salience classrooms would express greater reluctance to play with other-sex children than would children in the low-salience classrooms. As a third way to evaluate children's interest in own- versus other-sex peers, we collected observational data on children's peer play. We predicted that children in the high-salience (but not low-salience) classrooms would show a significant decrease in play with other-sex peers over the 2-week period. Measures in the present study were designed so that in- and out-group biases could be assessed independently (i.e., children could show positive in-group attitudes without showing negative out-group attitudes, and vice versa). Researchers have suggested a primacy of in-group preference compared to out-group derogation (Aboud & Amato, 2001; Brewer, 1999). If children's preference for in-group members is strongly established by the early preschool years whereas negative attitudes toward out-group members develop somewhat later, then an experimental manipulation in the preschool years would be more likely to increase negative attitudes toward out-group members rather than influence already-established positive attitudes to in-group members.

The predictions described earlier concern children's gender attitudes about others and the consequences of those attitudes (i.e., in-group and out-group biases). Another aspect of gender development concerns the gendered nature of children's own interests, for example, whether children favor toys and educational or occupational pathways that are culturally viewed as masculine or feminine. Past research has suggested that children's gendered personal interests are generally resistant to short experimental interventions, even when those interventions have a significant impact on their beliefs about what others should do (e.g., Bigler, 1995; Bigler & Liben, 1990). To examine whether a similar pattern of results would hold here, we also collected pre- and posttest data on personal interests in culturally stereotyped activities and occupations.

Method

Participants and School Context

Participants were 57 children ranging in age from 3 years 1 month to 5 years 6 months (M = 4.7 years; SD = 0.65 years). Children were roughly evenly divided between two preschools, each enrolling approximately equal numbers of boys and girls (14 boys and 16 girls in one school; 14 boys and 13 girls in the other). The majority of participants were European American from middle-class backgrounds. Informed consent was obtained from the directors of each school and teachers in each classroom. All parents and children were informed about data collection (interviews and observations) by letter and given the opportunity to opt out of the research activities if desired. None of the parents or children declined to participate.

The two schools (four classrooms) were located in a mid-sized city in the Southwest and were similar along important dimensions (e.g., teacher education, class size, teacher–child ratio, populations served, policies implemented, and classroom arrangement). Despite similarities, however, there are always differences between any two schools and between any two classrooms within a given school and grade (e.g., different teachers, different peers). Thus, the design included both pre- and posttests on critical measures so that analyses could take into account any initial differences between children in the two conditions.

Classroom Conditions

Classrooms in the high-salience condition were designed to make gender salient by exposing children to frequent uses of gender classifications in their environment. Following procedures used by Bigler (1995), teachers were encouraged to make frequent use of gender through physical separation (e.g., lining children up by sex), classroom organization (e.g., posting separate boys' and girls' bulletin boards), and gender-specific language (e.g., "I need a girl to pass out the markers" and "Good morning boys and girls"). Although simple statements or requests from a teacher using gender might be interpreted by the child as implying competition, we specifically asked teachers to avoid using gender distinctions for rewards or competitive events. Thus, teachers were asked to limit their use of gender to labeling and classroom organization, and explicitly asked to treat groups equally and to avoid encouraging competition between boys and girls (e.g., we asked teachers to avoid comments such as: "The boys are being quieter so they can line up" or "Let's see who can clean up faster, boys or girls").

Teachers in the low-salience classrooms were given no instructions about changing their behaviors in any way. Importantly, the ongoing policy in both preschools was to avoid using gendered language and organization in the classroom, and thus, children in both conditions had a similar classroom history with the exception of the 2-week period of the study proper. Researchers observed the classrooms every few days over the 2 weeks to observe whether teachers were continuing to use gender (or not) as requested. Indeed, teachers in the high-salience classrooms followed instructions by using gendered language and separating their classroom activities according to gender, whereas teachers in the low-salience classrooms did not organize their classrooms by gender.

Assignment to condition was made at the level of the school rather than at the level of classroom. One reason for this decision was the practical need to meet the administrative needs of the schools, which required having consistent expectations for teachers. Additionally, it carried two design benefits. First, it ensured consistent behaviors among teachers who sometimes move between classrooms or interact with children outside their assigned classroom. Second, it avoided the problem of contamination effects across classrooms, a problem that has been noted in earlier school-based intergroup research (Patterson & Bigler, 2006).

Procedure Overview

Children were interviewed individually both before and after the classroom manipulation with measures described next. In addition and also as explained in more detail later, children were observed during their normal classroom play periods in sessions at the beginning and end of the classroom manipulation. Following the 2-week period and the administration of all measures, children participated in a debriefing and educational program administered by both teachers and experimenters. This debriefing program was included in an effort to counteract any possible increase in stereotyping and to help children understand prejudice and stereotypes. During the program, puppets, pictures, and posters were used to emphasize similarities and differences among people that were not based on gender. Although we would have liked to have administered delayed assessments of children's gender stereotypes to study long-term effects of the classroom condition and the success of debriefing, practical limitations on the time that the school could devote to the research precluded adding additional assessments to the study.

Gender Attitudes

Children's endorsements of cultural gender stereotypes were assessed before and after the intervention period by the activity and occupation subscales of the Preschool Occupation, Activity, and Trait–Attitude Measure (POAT–AM), developed as a part of a suite of sex-typing measures (see Liben & Bigler, 2002). In this measure, children are shown pictures of activities or occupations, and for each item asked if men/boys, women/girls, or both men and women "should" perform it. Children were asked to respond to 66 occupations and activities, including 22 culturally masculine (e.g., use tools, be a firefighter), 20 culturally feminine (e.g., play with dolls, be a dancer), and 24 neutral (e.g., fly a kite, be a writer) items by pointing to one of three cards to show who they believed should do the activity. The three cards showed schematic (silhouette) pictures of people, with one card showing a man and boy, another showing a woman and girl, and the third containing all of these figures. Scores for this measure are the number of "both men and women" responses. Thus, lower numbers of "both" responses indicate higher endorsement of cultural gender stereotypes and less gender flexibility.

Peer Play

Familiar-peer ratings. To assess children's interest in playing with own- versus other-sex peers at both pre- and posttest, children were shown photographs of each of their classmates. For each photograph, the child was asked, "How much would you like to play with [name of classmate]?" Children gave their responses by pointing to one of three faces that comprised a 3-point scale. The faces included negative, neutral, and happy expressions, and were explained as meaning they had no interest at all, some interest, or strong interest. Two scores were calculated for each participant, one averaging ratings of children of their own sex, and the other averaging ratings of children of the other sex.

Unfamiliar-peer preference. An additional measure of children's gender-based peer play preferences was administered at posttest only. In this task, children were shown three photographs of groups of unfamiliar peers, one showing all boys, one showing all girls, and the third showing both boys and girls. Each child was told, "These are children from another school," and asked, "If you were to go to that other school, which group of kids would you like to play with?"

Peer play observations. Children were observed during indoor free play periods through a one-way mirror in each classroom. Observations were conducted during free play periods to ensure that teachers were not assigning children to groups in any way. Based on procedures developed by Martin and Fabes (2001), raters observed children sequentially in 15-s units by following a randomly ordered list of children in the classroom. Once raters had observed each child on the list, they started again at the top of the list, until there were three observational periods for each target child on each of 4 days.

Two observers independently noted the number of own- and other-sex peers the child played with during each of the observational periods. There was high reliability between coders on the number of boys and girls with whom the child played (interclass correlations = .96 and .93, respectively). Data from the primary observer were used in the rare cases of disagreement. Two scores were calculated for each period (the beginning and the end of the study): One score was the number of own-sex children and the other score was the number of other-sex children with whom the child played, averaged over the six observations (three observations for each of 2 days at each time period). The pretest observations were calculated from 2 days of observations made just before and as the classroom manipulation was beginning, and the posttest observations were calculated from 2 days of observations made just as and after the classroom manipulation was ending.

Personal Interests

Children's own gender-linked interests were assessed with the activity and occupation subscales of the POAT–Personal Measure (POAT–PM; see Liben & Bigler, 2002). In the POAT–PM, children are asked to indicate the strength of their own interests in various occupations and activities by pointing to one of three faces described earlier for the peer rating measure. Following standard administration procedures, the POAT–PM was administered prior to the POAT–AM to minimize cross-measure contamination.

Instructions were explained with a gender-neutral item, "How much would you like to eat ice cream?" Once children understood the instructions, they were shown the pictures for the POAT–PM proper, and for each item they were asked, "How much would you like to ____?" Responses of *no interest* were scored as 1, *some interest* as 2, and *strong interest* as 3. The dependent measures were calculated separately for masculine and feminine items and were computed as the total number of points awarded divided by the total number of items in that category (i.e., masculine or feminine).

Results

Overview and Preliminary Analyses

Results are described in three major sections that present, first, data on children's gender-stereotyped attitudes; second, data related to children's interest in or observed play with peers of their own or the other sex; and, third, data on children's own interests in stereotypically masculine versus feminine activities and occupations.

Given the relatively narrow range of ages of participants, we had no hypotheses with respect to age differences within our sample. Nevertheless, we conducted preliminary analyses to check for possible age effects both with respect to the way that measures were functioning (e.g., reliability of the POAT scales) and with respect to the effects of the experimental manipulation. The measures were comparably successful for younger and older groups (ages 3.1–4.3 vs. 4.4–5.5, respectively) and effects did not vary with age either in main effects or in interactions. Therefore, results reported are based on the entire sample.

In a second preliminary analysis, we examined correlations between pairs of peer variables to evaluate whether our dependent measures were tapping redundant constructs. Correlations were uniformly low, suggesting that as intended, the various measures were tapping different aspects of gender-related cognitions and behaviors. Thus, results are presented separately for each measure below.

Gender Attitudes

The dependent variable used to assess gender stereotypes was the total number of "both" (i.e., gender-flexible) responses given to masculine and feminine items on the POAT–AM. Given that the POAT–AM contains 22 masculine and 20 feminine items, scores could range from 0 to 42, with higher scores indicating more flexibility (i.e., lower gender stereotyping). Scores were analyzed with a repeated measures analysis of variance (ANOVA) in which between-subjects variables were condition (low vs. high salience) and participant sex (boys vs. girls), and the within-subjects variable was time (pre- vs. posttest). When appropriate, t tests were used as follow-up tests. Differences reported as significant were $p < .05$ or better.

Analyses showed a significant interaction between condition and time, $F(1, 53) = 17.85$, $p < .001$, $\eta_p^2 = .25$. As shown in Figure 1, although in the low-salience condition there was no significant change in gender-stereotyped attitudes from pre- to posttest, M (SD) = 14.46 (7.14) versus

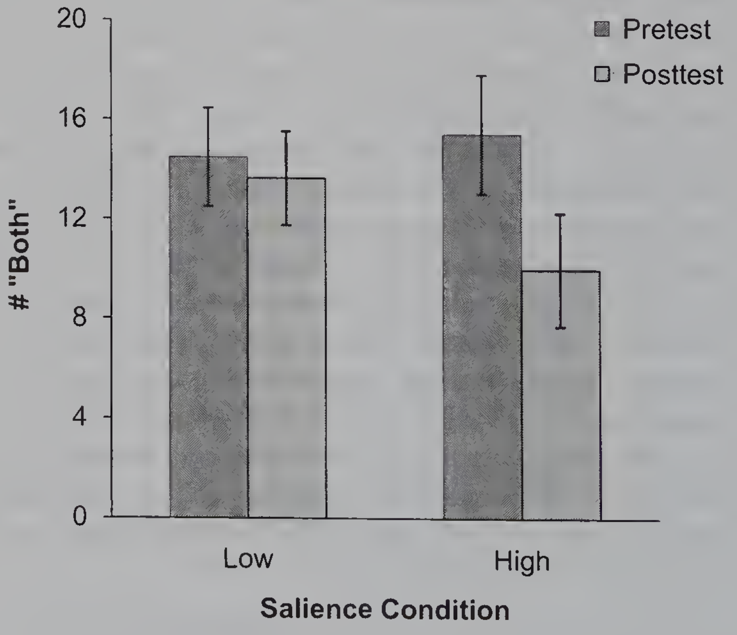

Figure 1. Mean numbers (and standard errors) of "both" (flexible) responses on the POAT–AM gender attitude measure by condition and time.
Note. Higher scores indicate greater gender flexibility or lower gender stereotypes (maximum score = 42).

13.61 (8.13), in the high-salience condition there was a significant drop in the number of flexible "both" responses from pre- to posttest, *M* (*SD*) = 15.37 (6.99) versus 9.94 (6.18), *d* = 0.12, indicating an increase in gender stereotypes. Also significant was the interaction between time and participant sex, *F*(1, 53) = 5.75, *p* = .020, η_p^2 = .09. The drop in the number of "both" responses over time was not significant in boys, 14.07 (7.00) versus 12.00 (8.00), but was significant in girls, 18.89 (6.23) versus 13.14 (8.15), *d* = 0.70.

Peer Play

Familiar-peer ratings. To examine children's ratings of interest in playing with familiar peers, the average ratings of boy and girl classmates served as the dependent measure in a repeated measures ANOVA. Between-subjects variables were condition (low vs. high salience) and participant sex (boys vs. girls), and within-subjects variables were time (pre- vs. posttest) and peer type (own vs. other sex).

Analyses revealed a significant three-way interaction among condition, time, and peer type, *F*(1, 48) = 8.46, *p* = .005, η_p^2 = .14, depicted graphically in Figure 2. In the low-salience condition, there was no significant change in other-sex peer ratings between pre- and posttest, *M* (*SD*) = 2.21 (0.47) versus 2.36 (0.37), whereas in the high-salience condition, there was a significant decrease in other-sex ratings over time, *M* (*SD*) = 2.09 (0.59) versus 1.48 (0.36), *d* = 1.03. Subsumed by the three-way interaction were two-way interactions between time and condition, *F*(1, 48) = 14.26, *p* < .001, η_p^2 = .22, and between peer type and condition, *F*(1, 48) = 16.39, *p* < .001, η_p^2 = .26.

Unfamiliar-peer preference. The dependent variable for assessing interest in playing with unfamiliar peers was the type of group selected, that is, the participant's selection of an own-sex group (i.e., the boy-only group for boys or the girl-only group for girls) versus an other-sex group (i.e., either the other- or the mixed-sex group). In both the high- and low-salience groups, only 1% of children chose to play with the other-sex only groups (i.e., those with all boys or all girls). For the purpose of analyses, other- and mixed-sex groups were pooled given that the important question concerned the child's willingness to play with the other sex. Data showed that 37% of children in the low-salience condition chose to play with a group that included children of the other sex compared to only 13% in the high-salience condition, a marginal effect of condition, $\chi^2(1) = 3.71$, *p* = .054.

Peer play observations. To assess children's observed peer play, we calculated average numbers of own- and other-sex peers per observational time unit (15 s). Play with only other-sex and mixed-sex children was collapsed for statistical purposes to cover play with any type of play with other-sex peers. A repeated measures ANOVA was conducted in which between-subjects variables were condition (low- vs. high-salience) and participant sex (boys vs. girls), and within-subjects variables were time (beginning vs. end of 2-week period) and type of peer (own- vs. other-sex).

Analyses revealed a significant three-way interaction among condition, time, and type of peer, *F*(1, 47) = 25.46, *p* < .001, η_p^2 = .35, shown in Figure 3. As may be seen in the figure, children in the low-salience condition showed no significant change in play with other-sex peers between the beginning and end of the 2-week period, *M* (*SD*) = 0.64 (0.30) versus 0.74 (0.39), whereas children in the high-salience condition showed a significant decrease in the amount of play with other-sex peers over time *M* (*SD*) = 0.92 (0.41) versus 0.26 (0.19), *d* = 1.3. Subsumed by the three-way interaction were a marginal two-way interaction between condition and time, *F*(1, 47) = 3.90,

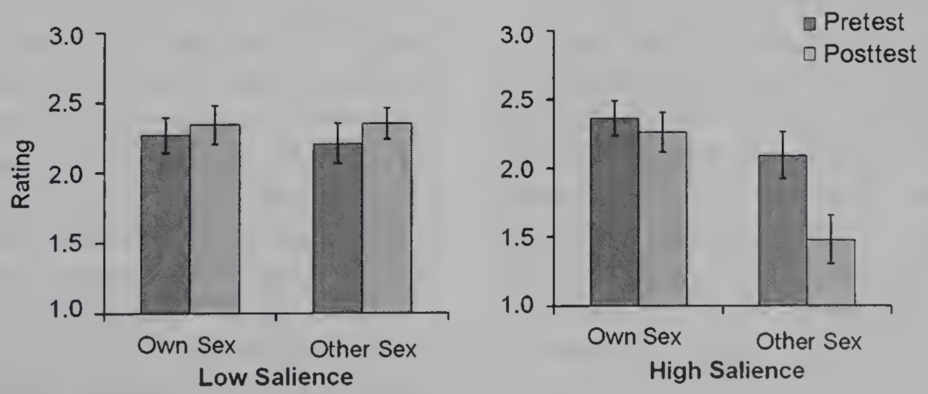

Figure 2. Mean ratings (and standard errors) of children's interest in playing with familiar peers by condition, peer type, and time (most positive rating = 3).

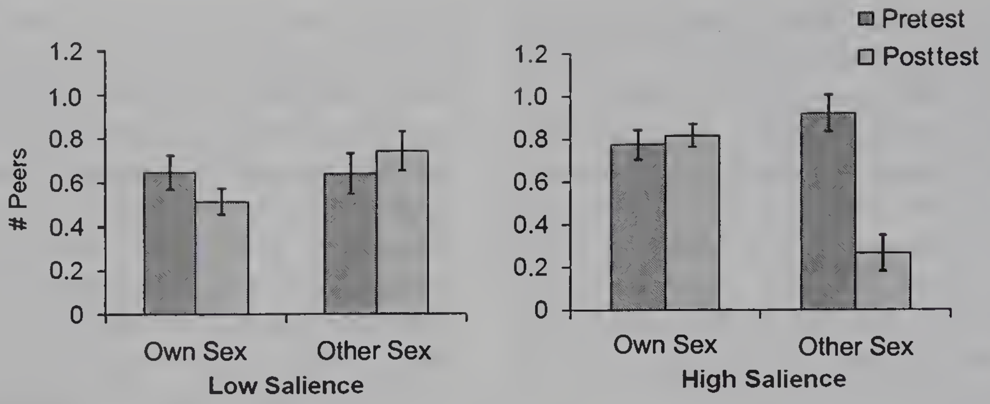

Figure 3. Number of peers (and standard errors) played with, on average, during 15-s observational units by condition, peer type, and time.

$p = .054$, $\eta_p^2 = .08$, and a two-way interaction between time and type of peer, $F(1, 47) = 6.04$, $p = .018$, $\eta_p^2 = .11$.

Personal Interests

As explained earlier, personal interest in culturally gender-stereotyped activities and occupations was assessed by the POAT–PM. Average interest scores (on a 3-point scale) were calculated separately for masculine and feminine items and then analyzed with an ANOVA. Between-subjects variables were condition (low vs. high salience) and participant sex (boys vs. girls), and within-subjects variables were time (pre- vs. posttest) and item type (masculine vs. feminine).

Analyses revealed a significant interaction between participant sex and item type, $F(1, 48) = 205.60$, $p < .001$, $\eta_p^2 = .81$. As expected, boys preferred masculine items more than feminine items, 2.50 (0.24) versus 1.86 (0.28), $d = 2.2$, whereas girls preferred feminine items more than masculine items, 2.48 (0.21) versus 2.11 (0.35), $d = 1.05$. No other main effects or interactions were significant.

Discussion

The major purpose of this research was to test predictions derived from developmental intergroup theory concerning the impact of environmental qualities on the development of stereotypes and prejudices. Specifically, we tested the predictions that making gender more salient in the classroom would lead first, to stronger gender stereotypes and second, to stronger intergroup biases in preschool children. Data provided compelling support for both predictions.

With respect to gender stereotypes, data from the POAT–AM measure showed that children in classrooms in which gender was made salient expressed significantly more highly stereotyped attitudes at posttest than they had at pretest. A comparable change did not occur among children in the low-salience classrooms, indicating that increased stereotyping in the high-salience condition cannot be attributed merely to retesting effects or to the passage of time.

With respect to in-group versus out-group biases, data from several directions converge on the conclusion that children who experienced high-salience classrooms developed increased rejection or avoidance of the out-group (i.e., the other sex). One line of evidence for this conclusion comes from the familiar-peer ratings. Children in the high- (but not low-) salience condition showed a pre- to posttest decrement in their ratings of how much they would like to play with their other-sex classmates. A second line of evidence comes from the unfamiliar-peer preference measure given at posttest. This measure revealed that children in the high-salience classrooms were marginally ($p = .054$) less likely than children in the low-salience classrooms to say they would like to play with groups of unfamiliar peers that included other-sex children. Finally, a third line of evidence derives from observational data on children's free play in the classroom which revealed that over the 2-week period of the study, children in the high-salience condition showed a significant decrease in their play with other-sex peers whereas children in the low-salience condition showed no such decline.

It is interesting that despite the fact that the measures used could have revealed increased favoritism toward the in-group as well as increased rejection of the out-group, our data showed evidence for the latter only. That is, even in the high-salience group, there were no significant increments over time in children's ratings of own-sex peers or in their actual play with own-sex peers. In earlier work on race-based social groups, Cameron et al. (2001) found that preschool-aged children held positive in-group bias toward their own racial group, but did not demonstrate negative out-group evaluations, suggesting a primacy for in-group bias. Aboud (2003) found that in-group positivity and out-group negativity were reciprocally correlated for children with little personal experience with out-group members (i.e., from a racially homogenous school), but in-group positivity and out-group negativity were not reciprocal for children from racially heterogeneous school. In the present study—with gender-defined social groups and coeducational classes—children had experienced extensive daily interactions with other-sex peers, thus offering no reason to expect a reciprocal association. However, it is also risky to assume equivalent processes for groups defined by race and gender, and thus it would be important to continue to explore both in-group and out-group processes and the way that they may be linked in the domain of gender.

Before leaving the discussion of the data relevant to in-group and out-group bias, it is important to point out that when children were tested under the conditions of their normal classroom environment (i.e., at both pre- and posttest for the low-salience condition; at pretest for the high-salience condition), the data showed no evidence of rating own-sex children higher than other-sex children (Figure 2) or of playing more with own-sex children than other-sex children (Figure 3). Given that other investigators have found evidence of own-sex preferences in preschool settings (e.g., Martin & Fabes, 2001), one possible interpretation of the current data is that preschools that assiduously avoid gender-based divisions or language in their classrooms indeed prevent (or postpone) in-group biases observed in other settings. The data may also reflect the egalitarian values of parents who enrolled their children in these schools.

Although more research is thus needed to learn precisely when and how in-group and out-group gender biases evolve, the data from the current study already demonstrate the role of social-group salience on bias, and bolster arguments made by others (Aboud, 2003; Allport, 1954; Brewer, 1999; Cameron et al., 2001) about the importance of assessing in-group and out-group biases with distinct measures.

Taken together, the findings on children's gender stereotypes and group bias extend earlier work with respect to both age and scope of effects of social-group salience. Earlier work (Bigler, 1995) had demonstrated that increasing gender salience had led to increased stereotypes in older (elementary school) children; the current data demonstrate that these forces operate even among younger children who have less advanced categorization skills. Recent research (Patterson & Bigler, 2006) had shown that highly visible, novel groups that had been defined by colored shirts led to stereotypes and group biases in preschool children. The current data demonstrate that similar effects result from increasing the salience of gender, even though it is already a social category well known to preschoolers (e.g., Ruble, Martin, & Berenbaum, 2006; Weinraub et al., 1984).

As in any study, many important questions remain for future research. One issue concerns how long the observed salience effects persist. As noted earlier, practical constraints prevented the inclusion of delayed posttests in this study. However, having now established immediate and dramatic effects of gender salience in the classroom, it becomes important for future research to address the degree to which such effects are long lasting, and to identify the factors that influence their longevity.

Another question concerns the associations among the outcome variables. We had selected a range of measures addressed to constructs hypothesized to be affected by the gender-salience manipulation. One measure (POAT–AM) was selected to assess the degree to which the child endorsed cultural gender-stereotyped attitudes about what others should do. Two measures (peer ratings and, at posttest only, the novel peer measure) were selected to assess children's cognitions about their interest in playing with others of their own and the other sex. One measure (play observation) was selected to study children's actual behavior with their own- and other-sex peers. All measures for which there were pre- and posttest data showed a significant impact of the manipulated classroom condition, and the posttest only novel peer measure showed a marginal effect of group. Thus, the data from the current study allow us to conclude that as hypothesized, increasing gender salience in the classroom affects a range of children's gender-related beliefs and behaviors. Remaining for later research with much larger samples is the intriguing and important question about how the various components of gender beliefs and behaviors are connected, in some cases, perhaps causally. For example, future research might examine whether a rise in gender stereotyping decreases children's willingness to play with children of the other sex, or whether there is an inverse pathway, or if perhaps each outcome is instead controlled by some other factor.

A clear implication of the findings already in hand is that schools should make it as unacceptable to use gender-specific language and divisions (e.g., ''Good morning boys and girls'') as it is to use race-specific language and divisions (e.g., ''Good morning Black children and White children''). There are ample anecdotal data that the former continues to occur in our educational system. For example, as this article was being written, the second author received a note from a former student reporting that she had worked over the summer in a preschool center ''and they actually split the children up for free play time, saying girls you can play this and boys you can play that, i.e., dolls and action figures'' (D. Russell, personal communication, October 7, 2008).

What also remains for future research is exploration of the cognitive mechanisms by which increased gender salience leads to greater gender stereotypes and out-group biases. As proposed by Bigler and Liben (2006, 2007), developmental intergroup theory posits that one causal mechanism for stereotyping lies in children's active attempts to assign meaning and correlates to social categories that are made salient in the environment. To test this position, it would be necessary to monitor children's cognitive processing (e.g., measure children's attention to implicit and explicit correlates of gender) over time under low- versus high-salience conditions.

Another potential causal mechanism involves the peer environment. Previous work has shown that peer groups provide a powerful context to socialize gender-linked play styles and preferences (Fabes, Martin, & Hanish, 2003; Maccoby & Jacklin, 1987). In a longitudinal study in preschool classrooms, Martin and Fabes (2001) found that children who were engaged in high levels of own-sex play at the beginning of the study showed more gender-typed play at the end of the study than did children who were engaged in low levels of own-sex play. They noted that over time, the play styles of each gender group became increasingly distinct.

Several aspects of our work showed that the high-gender-salience condition led children to reject other-sex peers, thereby increasing gender segregation. First, anecdotes reported by teachers in the high-salience condition suggest that children were quick to pick up on gender categorization and organize themselves by gender. One teacher, for example, noted that on the second day of the manipulation, without prompting from her, children established separate boys' and girls' snack tables. Second, the formal observational data on peer play showed that children in the high-salience condition became less likely to play with children of the other sex over time. To the degree that increased gender salience in the classroom led children to play less with members of the out-group, children would have even less occasion to be socialized into the play styles and preferences typical of the other sex, in turn exaggerating differences between gender groups. It is likely, given previous findings and our current study, that early gender segregation leads to two distinct gendered peer cultures, which, exacerbated over time, establish a script for later relationship styles and affect life decisions (Leaper, 1994).

In short, anecdotal data on children's classroom behaviors and systematic data on children's peer play suggest that much of the effect of the teachers' greater use of gender in the high-salience groups may have had its impact by inspiring children themselves to create a highly gendered environment. Another important direction for future research is therefore to observe, in detail, how the classroom environment (e.g., children's communication, segregation, and role playing) evolves under low- versus high-salience conditions.

Finally, the data from the current research add to the literature concerning the strong and persistent nature of children's own gendered interests. As expected, responses to the POAT–PM showed that children held sex-linked preferences, with boys preferring masculine items more than feminine items and girls preferring feminine items more than masculine items. There was no modification of this pattern as a function of gender-salience condition. The finding is consistent with earlier research (e.g., Bigler, 1995; Bigler & Liben, 1990) showing that brief experimental interventions leave children's own gendered interests and preferences unchanged even in the face of significant changes in children's beliefs about what others should do. Such findings suggest that modifying children's gender stereotypes will not be sufficient to expand children's educational and occupational choices (e.g., encouraging more girls and women to pursue science-related hobbies, coursework, and careers) and that more directed intervention strategies are needed. It is plausible that the 2-week intervention was not long enough to affect children's own interests and that over a longer period of time, children would be likely to internalize the gender stereotypes and show more gender-linked interests.

In conclusion, the findings from the present research have important implications for both theory and practice. At the theoretical level, data provide support for a core prediction of developmental intergroup theory (Bigler & Liben, 2006, 2007), which posits that social-group salience plays an important role in the formation of stereotypes and biases. At the practical level, data demonstrate that there is a pervasive, powerful, and remarkably quick effect of making gender salient in the classroom. The current study highlights the impact in one area of a child's environment (the classroom), but one would also expect a strong influence of the attention to social-group categories in the home (e.g., different chores for male and female members of the household) and in the broader culture (e.g., different professional sports leagues) as well. Although there is much to learn about the mechanisms by which increasing the salience of group membership operates, the current research demonstrates the importance of minimizing attention to social-group divisions in young children's classroom environments, even for social-group divisions, like gender, that are already visible and salient in the society at large.

Race Salience and Essentialist Thinking in Racial Stereotype Development

Kristin Pauker

Nalini Ambady
Tufts University

Evan P. Apfelbaum
Northwestern University

The authors explored the emergence and antecedents of racial stereotyping in 89 children ages 3–10 years. Children completed a number of matching and sorting tasks, including a measure designed to assess their knowledge and application of both positive and negative in-group and out-group stereotypes. Results indicate that children start to apply stereotypes to the out-group starting around 6 years of age. Controlling for a number of factors, 2 predictors contributed significantly toward uniquely explaining the use of these stereotypes: race salience (i.e., seeing and organizing by race) and essentialist thinking (i.e., believing that race cannot change). These results provide insight into how and when real-world interventions aimed at altering the acquisition of racial stereotypes may be implemented.

Young children possess a number of abilities that may serve as the foundation for learning racial knowledge. Three-month-old infants can discriminate perceptually between different racial groups (Bar-Haim, Ziv, Lamy, & Hodes, 2006; Kelly et al., 2005), preferring to look at faces that belong to a familiar racial group. By 3–4 years of age, children can sort people by race (Aboud, 1988; Nesdale, 2001), and soon after, those in the ethnic majority group (e.g., European American children in the United States) show signs of implicit and explicit in-group preferences (Baron & Banaji, 2006; Cameron, Alvarez, Ruble, & Fuligni, 2001; Nesdale, 2004). Recent work has explored several variables underlying biased group attitudes, such as the role of categorization (Bigler, Jones, & Lobliner, 1997; Patterson & Bigler, 2006) and status (Bigler, Brown, & Markell, 2001; Nesdale & Flesser, 2001). However, despite notable research exploring children's racial attitudes, relatively little work has investigated the emergence and antecedents of children's racial stereotyping.

Much of past research exploring children's racial stereotyping has muddled the distinction between attitudes and stereotypes. Social psychologists have defined stereotypes as *cognitive* structures composed of consensual knowledge, beliefs, and expectations about social groups that may result in *both* positive and negative associations for a single specific group (Hamilton & Trolier, 1986). Stereotypes are thus distinct from racial attitudes, which reflect affective evaluations or preferences, where one group is consistently considered more positively and another more negatively. Measures conceived with the intent to measure stereotyping, such as "trait stereotyping," often measure a construct more akin to attitudes (see Ruble et al., 2004). We attempted to clarify the literature on children's stereotyping by investigating how children learn both positive and negative stereotypes about their in-group and out-group.

Determining *when* children begin to use racial stereotypes is essential for understanding their developmental trajectory. Research has established that racial stereotyping occurs in early adolescents (Blake & Dennis, 1943; Maykovich, 1972; Rowley, Kurtz-Costes, Mistry, & Feagans, 2007); however,

---

We are extremely grateful to all the children, parents, teachers, and administrators who helped make this project possible. We would also like to thank Archana Asundi, Jillian Russo, Megan Oswald, Monica Malowney, Robyn Yano, and Sara Kaplan for their assistance with data collection and coding. This research was supported by a Jacob K. Javits Fellowship to Kristin Pauker and National Institute of Health Award (R01 MH070833-02) granted to Nalini Ambady.

limited research exists with younger children, especially those below 10 years of age. Thus, we set out to systematically explore children's use of stereotypes pertaining to European American, African American, and Asian American individuals beginning at 3 years—the youngest age at which children have been reported to exhibit the ability to sort by race (Nesdale, 2001)—a necessary precursor to racial stereotyping. By exploring stereotyping among children 3–10 years of age, we were able to encompass an age range wide enough both to examine the developmental acquisition and eventual application of such stereotypes.

Equally essential to understanding racial stereotype development is determining *what* factors facilitate the emergence of these stereotypes. The few studies that have explored children's racial stereotypes, as defined before, have either concentrated on the behavioral consequences of stereotype awareness (Ambady, Shih, Kim, & Pittinsky, 2001; Apfelbaum, Pauker, Ambady, Sommers, & Norton, 2008; McKown & Weinstein, 2003) or the content of stereotypes pertaining to a few specific groups (Bar-Tal, 1996; Bigler, Averhart, & Liben, 2003; Corenblum, 2003). Far less attention has been devoted to the social and cognitive variables associated with racial stereotype development.

Predictors of Stereotyping

Our understanding of social development can greatly benefit from integrating developmental and social psychological approaches (Bigler & Liben, 2007; Olson & Dweck, 2008). In one such integrative approach, Bigler and Liben (2007) propose that three core processes contribute to the formation of social stereotypes and prejudice: (a) establishing the psychological salience of different person attributes, (b) categorizing individuals by salient dimensions, and (c) developing sets of traits, behaviors, and emotions that are associated with particular salient social groups. Additionally, they hypothesize key factors—perceptual discriminability, proportional group size, and explicit and implicit use—shape the operation of psychological salience, the first of these core processes. Once a dimension becomes salient, they suggest that essentialism, in-group bias, and explicit and implicit attributions mold the development of stereotyping and prejudice pertaining to that dimension. We focused on two components this model suggests should affect racial stereotyping: race salience and essentialist thinking.

Race Salience

Racial stereotyping must be preceded by an understanding that race is a meaningful basis for social categorization. Merely noticing a perceptual difference by which one *can* sort people does not mean this difference will be perceived as a meaningful, psychologically salient dimension. Labeling and both explicit and implicit use of a category increase its salience (Bigler et al., 1997; Patterson & Bigler, 2006). For example, children may notice that shirt color is a dimension by which they can sort people, but they may not use it until they are engaged in a capture-the-flag game where shirt color denotes team members. Subsequently, children start to organize their world based on salient dimensions and infer that any observed differences in behavior must be caused by inherent group differences (Bigler & Liben, 2007). Returning to our example, if the team in blue beats the team in red in three consecutive games, children may infer those on the blue team are inherently athletic. Thus, after a category has become psychologically salient to a child, essentialist thinking may foster stereotype development.

Essentialist Thinking

Essentialist thinking—the tendency to think of categories as immutable and informative—is grounded in the belief that certain categories have important underlying essences that define their nature and properties (Gelman, 2003; Medin & Ortony, 1989). A number of studies with adults have linked essentialist beliefs to stereotyping (e.g., Plaks, Stroessner, Dweck, & Sherman, 2001; Yzerbyt, Corneille, & Estrada, 2001; Yzerbyt, Rocher, & Schadron, 1997). Essentialist beliefs even predict racial stereotyping in adults to a greater extent than, and independent of, a number of established individual difference measures known to be associated with stereotyping (Bastian & Haslam, 2006; Levy, Stroessner, & Dweck, 1998).

While studies show children essentialize both animal (e.g., Gelman & Wellman, 1991) and human (e.g., race and gender; Hirschfeld, 1995; Taylor, 1996) categories, few have explored the social consequences of essentialist thinking in children. In one of the few studies to address this issue, Levy and Dweck (1999) demonstrated that children who believed that people's personal characteristics were fixed and immutable stereotyped novel group members to a greater degree. Immutability is one of the central components of essentialist thinking, and thus it is likely to be an important factor in the emergence of children's racial stereotypes.

Children naturally achieve a state where they view categories through such an essentialist lens when they attain racial constancy—a social-cognitive transition defined by viewing racial group membership as immutable. Once children believe that their own and others' racial group membership is permanent, they may consequently search out explanations for perceived similarities within or differences between racial groups (Cameron et al., 2001). Rutland, Cameron, Bennett, and Ferrell (2005) recently demonstrated that preschool children's level of racial constancy was significantly related to their racial bias scores (see also Semaj, 1980). While racial constancy has been related to racial bias, it remains an open question as to whether racial constancy also impacts racial stereotyping. Thus, we examined a naturally occurring change in essentialist thinking—the achievement of racial constancy—as a predictor of children's racial stereotyping.

Considerable variability has been reported with respect to *when* children achieve racial constancy—some work suggests racial constancy does not emerge until at least 7 or 8 years (Aboud, 1988; Aboud & Ruble, 1987; Hughes, 1997) and other work reports children exhibiting such capacities as early as preschool (Hirschfeld, 1995). These studies may in fact be measuring different components of similar constructs. Children may have nascent theories about race in preschool but may not have an explicit understanding of a coherent essentialist theory about race until slightly later. Examining children's social reasoning often provides valuable insight into children's understanding of social concepts not available through simple forced-choice measures (e.g., Killen & Stangor, 2001; Ruble et al., 2007; Taylor, Rhodes, & Gelman, 2009). Drawing on this framework, we probed children's reasoning regarding racial constancy to gauge age-related changes in essentialist thinking and reasoning.

The Present Research

The present investigation focused on two primary aims. First, we examined the emergence of children's racial stereotypes. Second, we explored potential antecedents to their development.

Since children start to demonstrate ethnic and racial awareness as young as 3 or 4 years of age and reliably report a number of stereotypes by early adolescence, we chose to investigate racial stereotyping in children 3–10 years of age. Our measure included both positive and negative stereotypes associated with three racial groups: European American, African American, and Asian American, which we recoded into in-group relevant and out-group relevant stereotypes. We predicted most children would demonstrate racial stereotyping around 6 years, since (a) previous work has demonstrated children's awareness of race-related occupational stereotypes at 6 years of age (Bigler et al., 2003) and (b) children at this age either have reached or will soon reach several important social-cognitive milestones, including racial constancy (Ruble et al., 2004). Accordingly, we first explored in-group and out-group stereotypes across four age groups: a very young group where we expected little or no stereotyping (preschoolers: 3–5 years), an older group where we expected prevalent stereotyping (second to fourth graders: 7–10 years), and two narrower groups centered around 6 years (kindergarteners: 5–6 years, first graders: 6–7 years) where we expected stereotyping to emerge.

The timing of stereotype acquisition may also depend on a child's own group membership. We expected that by virtue of being the numerical minority, minority group members who are more psychologically salient and distinctive (McGuire & McGuire, 1988) will more often be the targets of racial stereotyping than proportionally larger (racial majority) groups (Bigler & Liben, 2007). Thus, we predicted that European American, racial majority group children should exhibit more stereotyping with age, but that they would primarily use out-group opposed to in-group stereotypes.

Next, we examined several factors predicted to contribute to the emergence of racial stereotyping. To control for children's level of cognitive development, we included a classic sorting task often employed as a measure of classification skills. This provided us with a measure of cognitive skill and an opportunity to assess children's spontaneous use of race as a sorting dimension. Children's use of race as a sorting dimension and their mention of race in a subsequent task in which they described an array of faces, served as measures of race salience. Finally, children completed a racial constancy task, which included a free-response question in which we coded their use of essentialist reasoning. While we expected both age and classification skill would be related to racial stereotyping, we predicted that two primary factors would contribute uniquely to the emergence of racial stereotype awareness in children: race salience and essentialist thinking in racial constancy.

Method

Participants and Design

A total of 89 children were recruited from the local community through mail solicitations to parents and from four suburban public elementary schools that serve middle- and upper-middle-income families outside Boston, Massachusetts. The return rate of initial letters sent out to the local community was 40%, and 90% of those parents agreed to participate. In the elementary schools, among consents sent home with students in participating classes, 75% gave written permission. These children's schools were predominantly European American (76%), with some Asian American (11%), African American (4%), and Latino American (9%) children; their neighborhoods also had a similar composition. The sample consisted of four age groups: preschoolers (3–5 years; $M = 3.73$ years, $SD = 0.37$; $n = 21$ [9 females]), kindergarteners (5–6 years; $M = 5.29$ years, $SD = 0.50$; $n = 36$ [14 females]), first graders (6–7 years; $M = 6.71$ years, $SD = 0.25$; $n = 16$ [9 females]), and second to fourth graders (7–10 years; $M = 8.97$, $SD = 1.32$; $n = 16$ [7 females]). Participants were mostly European American (89.9%), with a small representation of minority participants (4.5% Asian American, 5.6% Multiracial).

Measures and Procedure

Parents were informed of the study via letters sent home by school administrators or by phone for those children recruited from the community. Upon receipt of parental consent, individual children who provided verbal assent participated in a quiet location, separate from other children in the elementary school or separate from their parents. The experimenter led the participant through four tasks, assessing racial stereotyping, classification skill, race salience, and essentialist reasoning in racial constancy. To avoid contamination from tasks that were obviously about race (e.g., racial constancy) and to enable spontaneous assessment of children's use of race as a categorization dimension in earlier tasks (e.g., classification task), these tasks were always presented in the same order.

Racial Stereotyping

Forty-eight high-resolution photos of male children were arranged into 24 pairs. We used only male photographs for the racial stereotyping task because several of the stereotypes used are more strongly associated with males (e.g., Maddox & Gray, 2002; Niemann, Jennings, Rozelle, Baxter, & Sullivan, 1994). Photographs were taken from the Internet and an existing laboratory database and were pretested for perceived attractiveness, age, race, and emotionality. Adults ages 18–22 ($N = 30$) and children ages 6–10 ($N = 15$) rated the photos. Adults used a 7-point scale and children used a 5-point scale to rate attractiveness. For the remaining items, raters indicated their free response. Photos receiving extreme ratings of attractiveness or age were dropped, as were photos for which racial categorization was not reliably accurate. Each of the 48 final selected photos was cropped below the shoulders, gray-scaled, and pasted onto a uniform background before being placed into a photo album. The experimenter led the child through the photo album while narrating 24 brief behavioral episodes.

For each episode, participants were asked to select the child in the depicted pair that was most likely to have demonstrated a target behavior (see Ambady et al., 2001). Nine target episodes described behaviors that typify prevalent *negative* stereotypes about three racial groups: African Americans (i.e., stealing from others, acting aggressively, underperforming academically), Asian Americans (i.e., being shy, acting submissively, retaining foreign customs), and European Americans (i.e., bragging, ordering others around, excluding others). Nine target episodes described *positive* stereotypes about the same three racial groups: African Americans (i.e., being musical, playing basketball well, being rhythmic), Asian Americans (i.e., being hardworking, playing violin skillfully, excelling in math), and European Americans (i.e., being wealthy, receiving preferential treatment, acting as a leader). Younger children (3- to 4-year-olds) only heard a subset of the stereotypical episodes (the first two positive and negative episodes listed for each racial group, totaling six negative and six positive episodes), to increase the likelihood that their concentration would last through the whole task. Six nonstereotypical fillers described race-neutral behaviors (i.e., liking animals, playing outdoors, eating chocolate, listening to stories, making things with play-doh, playing on the swings). Stereotypical behaviors were chosen based on older children's (above 8 years) and early adolescents' open-ended racial stereotypes (Blake & Dennis, 1943; Maykovich, 1972; Zeligs, 1947) and commonly reported adult racial stereotypes (Lin, Kwan, Cheung, & Fiske, 2005; Madon et al., 2001; Niemann et al., 1994). The stereotypicality or neutrality of the episodes was validated through pretesting with adults.

We specifically chose to focus on racial stereotypes relevant to a school setting (e.g., academics, extracurricular activities, peer interactions), because not only may racial stereotypes limit children's potential in a number of academic and extracurricular domains, they may also exacerbate intergroup relations through enforcing self-segregation into "acceptable" stereotype-consistent domains (Kao, 2000).

For stereotypical episodes, we always displayed one photo of a child belonging to the racial group (African American, Asian American, or European American) targeted by the stereotype. The second photo was chosen from among the other racial groups with the stipulation that the photo chosen did not belong to the same racial group as the target photo. The racial group of the child not associated with the stereotype was randomized for each episode and counterbalanced across participants. This ensured that participants who belonged to one of the racial groups in the pair were not always making a decision that involved an in-group/out-group choice. For example, if a participant was European American, an African American stereotypical episode could include an in-group (European American) target and an out-group (African American) target or two out-group (Asian American and African American) targets. For filler episodes, the racial composition of the pairs was randomized. We counterbalanced the order in which episodes were presented and whether the target photo appeared on the left or the right. Additionally, we randomized the pairings of photo sets and episodes.

Participants practiced with two randomly selected filler episodes before moving on to the remaining 22 behavioral episodes. For example, in a behavioral episode used to gauge a positive African American stereotype, a participant would be told, "One of these children is really good at basketball. Everyone wants him on his team because they will win. Which of these boys do you think he probably is?" Participants were instructed to point to the child most likely to have demonstrated the behavior, and their responses were recorded. An answer was coded as stereotypical if a child picked the target in a stereotypical episode. We averaged participants' stereotyping scores across out-group episodes and in-group episodes. Thus, if a participant was European American, out-group stereotyping was composed of Asian American and African American episodes and in-group stereotyping was composed of European American episodes.

Classification Task

Using procedures reported in Bigler (1995), the classification task was composed of 16 photographs of people cropped at the waist who varied systematically on several dimensions: race (African American, European American), sex, age (children, adults), and facial expression (serious, laughing). The photographed individuals also differed with respect to a variety of other nonsystematic dimensions (e.g., clothing, posture).

The experimenter spread all the photos on a table and asked the participant to sort them into two groups such that, "people who go together are in the same pile." If they were able to successfully complete a sort, they were asked to explain their sort. After the initial sort, the experimenter asked the participant if there was an additional way to sort the photos. This continued until the participant could no longer think of dimensions upon which to sort the photos.

Children who did not complete a successful sort were given a score of 0. Children who were able to sort the stimuli according to one dimension but were not able to re-sort the stimuli in a new way were given a score of 1. Children who were able to complete two such sorts were given a score of 2 (see Bigler & Liben, 1993). When scoring the sorts, coders checked that each child's explanations for their sorts matched the piles they created. For this and all subsequent coding tasks, two experimenters independently coded the responses. Overall, interrater agreement was high (Cohen's $\kappa = .98$), and disagreements were resolved via discussion.

Race Salience

Race salience was gauged by two measures: sorting by race in the preceding classification task and racial justification. First, those who spontaneously sorted by race in any of their sorts in the preceding classification task were given a score of 1 and those who did not sort by race at all were given a score of 0 for the sort by race variable.

Second, we measured children's use of racial justification in a second task where they described sets of photos. In this task, two arrays of six same-gender photographs, one all-White and one racially diverse, were presented to participants, counterbalanced across trials. Participants were asked whether the people in the photographs were the same or different and why they were the same or different (see Semaj, 1976). We coded for participants' use of race or skin color as a reason for being different in the racially diverse set or as a reason for being the same in the all-White set. Children who acknowledged racial difference in either of the sets were given a score of 1 and those who did not were given a score of 0 for the racial justification variable.

The sort by race and racial justification variables were not combined into one index. Although they both indicate race salience, the first measure (sort by race) more clearly represents functional use of race, whereas the second measure (racial justification) more clearly represents noticing and describing a perceptual difference in the array. The stimuli used in the sort by race measure varied along many systematic dimensions. Thus, children's choice to sort by race meant that they preferentially used that dimension or perceived that dimension as more salient than the others, reflecting its functional use. In contrast, the stimuli used in the racial justification measure appeared similar on all dimensions, except for race, and we specifically asked children what made the pictures the same or different. Therefore, the stimuli intentionally highlighted racial differences and restricted available alternative descriptions. As a result, children's choice to report that they noticed racial differences did not involve making any trade-offs between other potential dimensions. Because of this conceptual difference, we kept the two measures separate since others have found that functional use of categories exacerbates intergroup bias compared to just noticing perceptual differences (Bigler, 1995; Bigler et al., 1997), and thus the two measures of race salience could differentially influence racial stereotyping.

Essentialist Thinking in Racial Constancy

Racial constancy was assessed both for judgments of the self and others, since we reasoned that such judgments might differentially predict a child's focus on in-group or out-group stereotypes. We modified previous tasks used to assess racial or gender constancy (Hirschfeld, 1995; Ruble et al., 2007; Semaj, 1980), targeting three core components of children's understanding of racial constancy: identification, stability, and consistency (Ruble et al., 2004).

Judgments of the self. Identification (i.e., correct identification of one's own category membership) was assessed using the question, "Are you a White big boy/girl or a Black big boy/girl?" Most participants were European American and received a White/Black comparison pair; however, if they were Asian American or multiracial, we asked their parent or teacher for the most appropriate term to use and used Black as the alternate category. Two questions were used to assess stability (i.e., understanding race remains constant over time): "When you were a baby, were you a White baby or a Black baby?" and "When you grow up to be a man/woman will you be a White man/woman or a Black man/woman?" Lastly, consistency (i.e., understanding race is consistent across superficial transformations) was assessed by the initial question, "If you really wanted to change your skin color to be a Black man/woman could you?" and a follow-up question to reveal the reasoning underlying their initial answer (e.g., "How would you do that?" or "Why not?").

Judgments of others. We assessed stability and consistency for judgments of others using photographs matched to the participant's gender. Again, we used two indicators to assess stability: First, participants saw either a photograph of a White or Black child above one White and one Black adult, and were asked, "When this child grows up, will they look more like this adult or that adult?" Second, participants saw a photograph of a White or Black adult above one White and one Black child, and were asked, "When this adult was little, did they look more like this [White] child or this [Black] child?" To assess consistency, participants were shown a picture of a White child and were asked the initial question, "If this child really wanted to be Black and change his/her skin color could he/she do that?" Children were then asked a follow-up question to reveal the reasoning underlying their initial answer (e.g., "How would he/she change?" or "Why can't he/she change?").

Racial constancy and essentialist reasoning. Children responses to the items relating to identification and stability were coded as correct (1) or incorrect (0). For the consistency item, we also took into account children's reasoning in coding their answer (see Ruble et al., 2007). First, children's underlying reasoning was coded for content. Children only received a (1) for the consistency item if the initial question was answered correctly *and* if the follow-up question indicated true constancy by utilizing essentialist reasoning (e.g., "He can't change. You're born one way and you can't change after that"). Finally, the scores were added together to form a composite score, with higher scores indicating a greater sense of racial constancy for the self or others.

In sum, we employed two types of broad measures: one type that gauged use of in-group and out-group stereotypes and a second type including an assortment of variables that gauged capacities we hypothesized to be associated with the emergence of such stereotype usage. The predictor variables included factors we wanted to control for (i.e., classification skill) and two main predictors of interest: race salience (i.e., sort by race, racial justification) and essentialist thinking (i.e., composite racial constancy score for self, composite racial constancy score for others, essentialist reasoning used in the racial constancy measures).

Results

Overview of Analyses

Our primary outcome of interest was participants' use of racial stereotypes, averaged across in-group and out-group relevant episodes. Recall, participants chose which child was most likely to exhibit a behavior, and each target episode was coded as in-group stereotype or out-group stereotype relevant. First, we explored potential age group differences in children's use of both positive and negative stereotypes associated with in-groups and out-groups using a three-way analysis of variance (ANOVA). Next, we employed hierarchical multiple regressions to examine the possibility that increased understanding of race salience and essentialist thinking in racial constancy may explain unique variance in children's racial stereotype development not accounted for by other variables, such as age and classification skill.

Stereotyping

To explore age group differences in positive and negative in-group and out-group stereotyping, we submitted the stereotyping scores averaged across items to a 2 (group: in-group, out-group) × 2 (valence: positive, negative) × 4 (age group: 3–5 years, 5–6 years, 6–7 years, 7–10 years) ANOVA, with repeated measures on the first two factors (see Table 1 for all means). In a first pass, we included sex and race of the participant in the analyses, but no differences were obtained as a function of sex, race, or any of their interactions so analyses collapsed across these variables. Notably, we also found no effects of valence or interactions with valence, *F*s < 0.53, *p*s > .47; thus, valence was not considered further. Only the main effect of age group, $F(3, 85) = 6.95$, $p < .001$, $\eta^2 = .20$, and the Group × Age Group interaction, $F(3, 85) = 3.14$, $p = .03$, $\eta^2 = .10$, were reliable. As displayed in Figure 1, children's stereotyping (both positive and negative) increased with age (main effect of age group), and children's in-group and out-group stereotyping emerged at different ages (Group × Age Group interaction). Follow-up simple-effects tests used to clarify this interaction indicated that age group differences were reliable for out-group, $F(3, 85) = 12.38$, $p < .0001$, $\eta^2 = .30$, but not in-group stereotypes, $F(3, 85) = 0.994$, $p = .40$, $\eta^2 = .03$. Bonferroni multiple comparisons used to explore the reliable age group differences in out-group stereotyping revealed that the two older groups exhibited more out-group stereotyping overall than the two younger groups. Specifically, two oldest groups ($p > .99$) and the two youngest groups ($p = .12$) did not differ significantly in their out-group stereotyping; however, the 6- to 7-year-olds ($M = 0.60$, $SD = 0.12$) exhibited more out-group stereotyping than 3- to 5-year-olds ($M = 0.38$, $SD = 0.18$, $p < .001$) and marginally more out-group stereotyping than 5- to 6-year-olds ($M = 0.49$, $SD = 0.15$, $p = .08$). The 7- to 10-year-olds ($M = 0.67$, $SD = 0.13$) exhibited more out-group stereotyping than either of the younger groups (*p*s < .001).

Table 1
In-Group and Out-Group Positive and Negative Stereotyping by Age Group

Stereotype valence (year-olds)	In-group stereotyping		Out-group stereotyping	
	Positive	Negative	Positive	Negative
3–5	0.55 (0.41)	0.59 (0.34)	0.35 (0.25)	0.41 (0.25)
5–6	0.53 (0.32)	0.57 (0.25)	0.47 (0.22)	0.50 (0.20)
6–7	0.55 (0.25)	0.49 (0.24)	0.60 (0.15)	0.60 (0.23)
7–10	0.60 (0.39)	0.69 (0.35)	0.67 (0.23)	0.67 (0.15)

Note. Values are given as *M* (*SD*).

Next, we ran one-sample *t* tests to determine whether racial stereotyping occurred at above-chance levels (50%). Despite a lack of relative differences across age groups for in-group stereotyping, children did use in-group stereotypes significantly above chance in the oldest age group (7–10 years; $M = 0.65$, $SD = 0.32$), $t(15) = 1.85$, $p = .04$, $r = .43$. Consistent with age group differences for out-group stereotyping, children in the two oldest age groups (6–7 years and 7–10 years; means reported before) utilized out-group stereotypes above chance, $t(15) = 3.38$, $p = .002$, $r = .66$ and $t(15) = 5.17$ $p < .0001$, $r = .80$, respectively. Given the strong differences in out-group stereo-

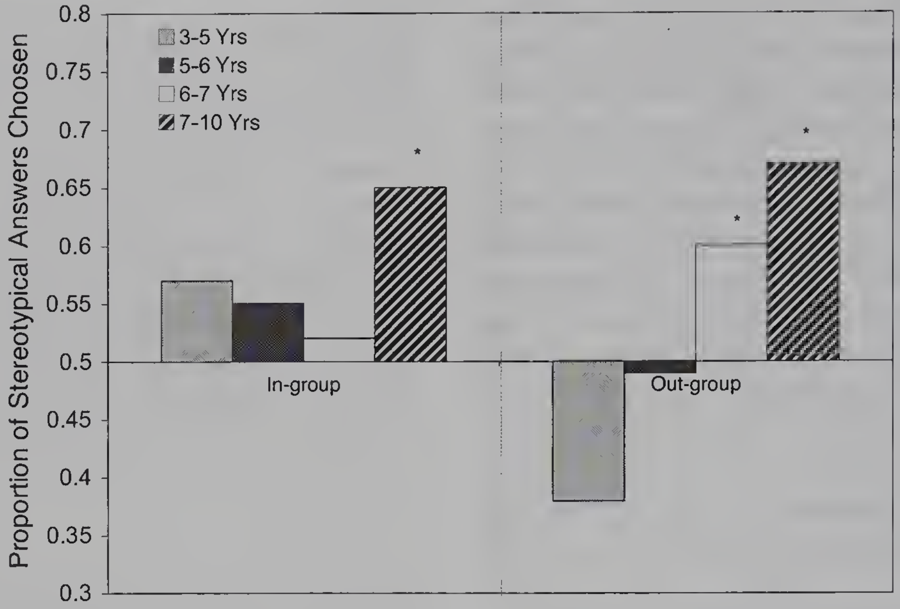

Figure 1. In-group and out-group stereotyping across age group. *Note.* Asterisk indicates a significant difference from chance.

typing and the lack of relative age group differences in in-group stereotyping, we sought to explore predictors of the emergence of out-group stereotyping. We were particularly interested in whether race salience and essentialist thinking in racial constancy uniquely predicted the emergence of out-group stereotypes.

Predictors of Out-Group Stereotyping

Age Group Differences in Predictors

Although not a central focus of this article, Table 2 provides means for age group differences across all of our predictors. One-way ANOVAs revealed children improved with age on all of our predictors ($Fs > 7.8$, $ps < .001$). At least half of the children exhibited perfect classification skills, sorted by race, and used a racial justification by 5–6 years of age. Racial constancy for self and others emerged slightly later, with the majority of children achieving a perfect score around 6–7 years of age.

Hierarchical Regression

Because of the significant positive relations between racial stereotyping and many of the predictors (Table 3), we performed multiple hierarchical regressions to determine the extent to which each predictor contributed unique variance in explaining patterns of out-group stereotyping. All regressions and correlations used age as a continuous variable. Seventy-four subjects were included in this analysis, since 12 subjects did not complete racial constancy measures due to time constraints, and an additional 3 subjects had incomplete answers for the racial justification task.

As displayed in Table 4, in Steps 1–3, we entered a number of factors for which we wanted to control in the regression: sex (0 = male, 1 = female), ethnic background (European American, Asian American, or Multiracial), children's age (in years), and classification skill (0, 1, 2). In Step 4, we entered our first predictors of interest: factors that indicated race salience (i.e., sorting by race and using a racial justification) coded as 0 = no and 1 = yes. In Step 5, we entered our final predictors of interest: factors that utilized essentialist thinking (i.e., children's racial constancy for self score and children's racial constancy for others score, respectively).

The model was significant at the second step, $F(4, 69) = 4.97$, $R^2 = .22$, $p = .001$, and remained significant across all subsequent steps through the final step, $F(9, 64) = 6.67$, $R^2 = .48$, $p < .001$. Once all variables were taken into account in the final model (see Table 4), none of the background variables (i.e., sex or race of the participant) significantly influenced out-group stereotyping. Although both age and classification skill contributed significantly to the model in earlier steps, once our predictors of interest were entered they no longer accounted for significant and unique proportions of variance in children's out-group stereotyping. As predicted, the factors that remained significant in the final model were those related to race salience and essentialist thinking: sorting by race ($\beta = .34$, $p = .003$), racial constancy for the self ($\beta = -.37$, $p = .005$), and racial constancy for others ($\beta = .49$, $p < .0001$). Note, however, that only one of our

measures of race salience remained significant in the final model, namely, sorting by race. Racial justification was not a significant predictor in the final model, which highlights perhaps the importance of functional use of race (i.e., using it to organize the world) opposed to merely noticing perceptual differences. In contrast, both predictors of racial constancy contributed significantly toward explaining out-group stereotyping. Specifically, racial constancy for others was associated with increased out-group stereotyping, whereas racial constancy for the self was associated with decreased out-group stereotyping. This suggests that it is essentialist thinking specific to out-groups—not essentialist thinking construed more broadly—that predicts out-group stereotyping.

Essentialist Reasoning

We delved further into children's reasoning in the racial constancy measures by coding their responses regarding whether they or another person could change their race. Responses were coded into one of four categories: no answer provided, superficial reasoning (e.g., "paint my skin," "change my clothes"), essentialist reasoning (e.g., "you can't change your skin," "White mommies have White babies"), or idiosyncratic reasoning (e.g., "grow," "don't want to change"). We then employed chi-square analyses to compare the frequency of each type of reasoning across age groups (3–5 years, 5–6 years, 6–7 years, 7–10 years). Sixty-eight subjects were included in this analysis, since 6

additional subjects completed the study without being asked why racial identity could or could not change.

Both judgments of the self, $\chi^2(9, n = 68) = 21.68$, $p = .01$, $\varphi = .56$, and others, $\chi^2(9, n = 68) = 31.04$, $p < .001$, $\varphi = .68$, changed across age groups. As displayed in Table 5, the patterns of reasoning across age groups was similar for judgments of both the self and others, except in the two younger groups. Reasoning among 3- to 5-year-olds was split between not providing a rationale for their answers reasoning ($M = 46.7\%$) and superficial reasoning ($M = 33.3\%$) for judgments about the self. These children generally did not provide a rationale for judgments about others ($M = 65.0\%$). Five- to 6-year-olds were split between not providing a rationale ($M = 20.0\%$), superficial reasoning ($M = 28.6\%$), and essentialist reasoning ($M = 37.1\%$) for judgments about the self. For judgments about others, however, these children used essentialist reasoning the most ($M = 46.7\%$) and superficial reasoning the second most ($M = 26.7\%$). For the two older age groups, children primarily used essentialist reasoning across both types of judgments (6- to 7-year-olds: $M_{\text{self}} = 78.6\%$, $M_{\text{other}} = 85.7\%$; 7- to 10-year-olds: $M_{\text{self}} = 75.0\%$, $M_{\text{other}} = 75.0\%$). However, only essentialist reasoning about *others* predicted out-group stereotyping, $r = .26$, $p = .03$. Essentialist reasoning about the *self* did not predict in-group or out-group stereotyping, $rs = -.07, .15$; both $ps > .21$.

Discussion

This research investigated the development and antecedents of children's racial stereotypes. These initial displays of stereotyping, around 6 years of age, were mainly restricted to out-group stereotypes but, importantly, involved the use of both positive and negative stereotypes. Our results provide empirical evidence that two critical factors—race salience and essentialist thinking—uniquely contribute to children's out-group stereotyping. Such a finding dovetails with recent theoretical work outlining the bases of racial stereotyping (Bigler & Liben, 2007). Consistent with a social-motivational model (e.g., Nesdale, 1999), neither age nor a measure of cognitive skill independently predicted out-group stereotyping. Children only oriented themselves toward out-group stereotypes once race became a functionally salient dimension and they developed a sense of the out-group as an essential category.

Stimulus salience has been shown to play a pivotal role in how individuals process social category information (Taylor, 1981). As race becomes a salient dimension to children, they may begin to organize information around racial categories and consequently form social stereotypes. Note that it was *not* children's mere mention of race as a descriptor (i.e., their use of a racial justification in describing a set of faces) that predicted the acquisition of out-group stereotypes but rather children's spontaneous use of race as a sorting dimension. In other words, children's functional *use* of race as an important organizing dimension in their world may facilitate racial stereotyping above and beyond children merely *noticing* perceptual racial differences (see Bigler et al., 1997; Bigler et al., 2001). As predicted, European American, racial majority children, who tend to have a less salient racial identity than racial minority children in the United States (McGuire & McGuire, 1988; Phinney, 1992), learned more stereotypes about out-group members before stereotypes about their own group. Thus, others' but not their own racial group membership was a distinctive dimension they noticed and used to formulate stereotypes.

Finally, children's understanding of racial constancy played a significant role in their use of out-group stereotypes, providing support for several theories that have proposed such a relation should exist (e.g., Aboud, 1988; Kohlberg, 1966). Racial constancy for *others* predicted increases in out-group stereotyping and racial constancy for the *self* predicted decreases in out-group stereotyping. One

Table 5

Percentage of Children Who Report Different Types of Reasoning to Explain Why or Why They Could Not Change to a Different Race

Type of reason (year-olds)	Racial constancy for self				Racial constancy for others			
	None	Superficial	Essentialist	Idiosyncratic	None	Superficial	Essentialist	Idiosyncratic
3–5	46.7	33.3	6.7	13.3	65.0	10.0	15.0	10.0
5–6	20.0	28.6	37.1	14.3	13.3	26.7	46.7	13.3
6–7	7.1	0.0	78.6	14.3	7.1	7.1	85.7	0.0
7–10	0.0	25.0	75.0	0.0	0.0	25.0	75.0	0.0

difference between the two tasks that could explain this difference in predictive power is that one relied primarily on images (racial constancy for others), whereas the other required knowledge of verbal labels (racial constancy for the self). While a plausible explanation, both tasks required knowledge of a verbal label to pass the task. Instead, we believe that this difference may be accounted for by the ease with which children essentialize the out-group versus the in-group and the effect that essentialist thinking applied to the out-group or in-group has on intergroup perceptions. Future research should certainly attempt to disentangle these factors and how they affect the emergence of racial stereotyping.

Although not a central focus of this study, children reliably demonstrated racial constancy, specifically for others, around 6 years of age. While this finding is inconsistent with Hirschfeld's (1995) work, it supports other studies on racial constancy (Rutland et al., 2005). Our measure also examined children's explanatory constructs, which may tap a more nuanced understanding of children's essentialist thinking, whereas Hirschfeld's method may tap a nascent biological theory. Importantly, this examination of children's explanatory constructs revealed that they steadily utilized more essentialist reasoning with increases in age, and that essentialist reasoning, specifically about others, predicted increases in out-group stereotyping. Thus, as children start to essentialize out-groups, they may also become aware of stereotypes associated with these groups.

The mechanisms involved in children's acquisition of racial stereotypes are likely to be complex and influenced by myriad factors. While race salience and essentialist thinking may provide the scaffolding for racial stereotype acquisition, the content of these stereotypes is drawn from cultural knowledge in the child's social milieu. For example, explicit information presented in books, TV, or educational curricula, and implicit or explicit information communicated by family, teachers, or friends may provide specific stereotype content (Bar-Tal, 1997). Additionally, implicit patterns of information available in the environment, such as segregation in schools or stratification of certain occupations in society may also furnish stereotype content (Bigler, Arthur, Hughes, & Patterson, 2008; Bigler & Liben, 2007). A number of additional factors, besides race salience and essentialist thinking are likely to be implicated in racial stereotyping as well (Bigler & Liben, 2007). For example, children's acquisition of racial stereotypes may be intertwined with their conceptions of status. Studies with adults have argued that more powerful groups (namely, the racial majority) attribute more stereotypes to those lower in the hierarchy to justify and legitimize their power (Yzerbyt et al., 1997). Young children are aware of status differentials (Bigler et al., 2003; Nesdale & Flesser, 2001) and, like adults, may try to rationalize observed inequities and status differences in society, serving to reinforce stereotypes of lower status groups.

While race salience may be a natural developmental acquisition in an environment where race is functionally important, racial stereotyping may not be an inevitable consequence of racial categorization or cognitive development. Certain social-contextual factors encourage more or less essentialist thinking about race, which provide scaffolding for children to make errors in judgment (i.e., stereotype) based on race. Future research should explore the types of contexts that minimize essentialist thinking about race and the types of educational strategies that curb the impact of pervasive explicit and implicit racial associations available in the environment. Moreover, this study suggests an implied underlying model of how age, cognitive skills, racial constancy, race salience, and essentialism work in concert to influence racial stereotyping. Future research should test this model explicitly using path analysis or structural equation modeling.

Relation Between Racial Stereotyping and Attitudes

While we have concentrated solely on racial stereotyping, racial attitudes surely constitute a sizable section of a child's racial knowledge toolbox. Children exhibit a reliable in-group bias early on, some as young as 3, well before the emergence of racial stereotyping documented in the present study (e.g., Nesdale, 2001). While many have interpreted this in-group bias as evidence that children possess negative racial attitudes, others have questioned the validity of this claim, arguing these findings reflect in-group preferences rather than true out-group derogation (e.g., Cameron et al., 2001; Pfeifer et al., 2007). Thus, while young children can label and organize their world by race early on—skills conducive to in-group preferences—they might not be able to symbolize an underlying concept and its associated attributes until they form a coherent essentialist theory about race.

The recognition of race as a psychologically salient dimension, early social preferences, and biological lay theories that all presumably develop in the preschool years provides a solid foundation upon which this developing system of social cognition—including both racial attitudes and stereotypes—can be built. Similar to racial stereotyping, a number of motivational factors may contribute to racial preferences becoming full-fledged racial attitudes, such as an explicit norm of prejudice in the environment or tension over limited resources (Nesdale, 2004). Thus, while children may have the foundation for racial attitudes and stereotypes early on, a host of motivational factors promote their consolidation into underlying concepts that guide behavior.

Limitations

Our sample included mainly racial majority (i.e., European American) children. The findings and models did not change when the sample of Asian American and multiracial children were removed from analyses. The one exception was that the comparison of in-group stereotyping to chance was no longer significant in the oldest age group—consistent with our conclusion that European American, majority children are primarily learning out-group stereotypes.

It will be important for future research to explore these processes with racial minority children. Since minorities in the United States have racial identities that are often perpetually salient and distinctive (McGuire & McGuire, 1988; Phinney, 1992), they may be more likely to learn both in-group relevant and out-group relevant stereotypes at an earlier age. Crucially, research should also consider how these processes work specifically with multiracial children whose existence challenges binary views of race. Racial constancy should not necessarily be thought of as the optimal "end-state." Multiracial children's racial identification often changes with context or time (Hitlin, Brown, & Elder, 2006), and they may develop more flexible theories about race that can mitigate the negative effects of stereotyping.

The diversity of children's surrounding environment is another important factor to consider. Our sample of children attended schools and lived in neighborhoods primarily composed of European Americans. Both school and neighborhood diversity may shape racial stereotyping in important ways, through changing children's individual cognitions (e.g., level of racial awareness), the function of stereotypes in that particular environment, and exposure to explicit and implicit racial associations. Future research should explore factors that predict the emergence of racial stereotypes in minority and multiracial populations and how structural aspects of the environment can shape the emergence of stereotyping. Additionally, although our study deliberately focused on a wide age range, future research should home in on factors that magnify race salience and exacerbate essentialist thinking in 3- to 6-year-olds.

On Preventing Stereotypes

Given that once stereotypes are formed they are highly resistant to change, especially in adults, and can affect critical real-world outcomes, such as children's academic performance (Ambady et al., 2001; McKown & Weinstein, 2003), our results lend important insight into age-appropriate interventions that may result in meaningful change. While change should be possible, since past studies have demonstrated that children's racial attitudes and preferences are malleable (e.g., Cameron, Rutland, & Brown, 2007; Katz & Zalk, 1978), less research has provided evidence for substantial change in children's racial stereotyping (but see Killen & Stangor, 2001). This may be due to a number of social-cognitive mechanisms that actually support stereotype maintenance in children (Bigler & Liben, 1993; Corenblum, 2003).

This research suggests that two potential factors play a key role in stereotyping racial out-groups: race salience and race-specific essentialist thinking.

Mitigating these factors should precipitate positive change. Interventions aiming to reduce race salience may be difficult to implement without making large-scale changes in a child's environment; however, recent studies with adults have demonstrated the ability to manipulate essentialist thinking about groups (e.g., Levy et al., 1998; Plaks et al., 2001). Thus, interventions aimed altering racial stereotypes may best be accomplished by directly manipulating children's pattern of thinking about racial groups. If children learn that race is not necessarily an immutable category and that even if the physicality of skin color is often immutable, it does not necessarily convey stable information about psychological attributes, perhaps they will be less susceptible to stereotyping others and to the adverse effects of stereotyping themselves.

Toddlers' Prosocial Behavior: From Instrumental to Empathic to Altruistic Helping

Margarita Svetlova, Sara R. Nichols, and Celia A. Brownell
University of Pittsburgh

The study explored how the meaning of prosocial behavior changes over toddlerhood. Sixty-five 18- and 30-month-olds could help an adult in 3 contexts: instrumental (action based), empathic (emotion based), and altruistic (costly). Children at both ages helped readily in instrumental tasks. For 18-month-olds, empathic helping was significantly more difficult than instrumental helping and required greater communication from the adult about her needs. Altruistic helping, which involved giving up an object of the child's own, was the most difficult for children at both ages. Findings suggest that over the 2nd year of life, prosocial behavior develops from relying on action understanding and explicit communications to understanding others' emotions from subtle cues. Developmental trajectories of social-cognitive and motivational components of early helping are discussed.

Human children begin to behave prosocially very early in life, before 2 years of age. Studies have documented 1-year-olds' abilities to comfort others in distress, participate in household tasks, and help adults by bringing or pointing to out-of-reach objects (Liszkowski, Carpenter, Striano, & Tomasello, 2006; Rheingold, 1982; Warneken & Tomasello, 2006, 2007; Zahn-Waxler, Radke-Yarrow, Wagner, & Chapman, 1992). These apparently prosocial acts, emerging so early in ontogeny, have been of interest to social, developmental, and evolutionary psychologists as possible precursors to such human-specific characteristics as concern for others, cooperation and, ultimately, altruism (Fehr & Rockenbach, 2004; Piliavin & Charng, 1990; Stevens & Hauser, 2004; Warneken & Tomasello, in press). The origins of these early behaviors, however, are not entirely understood, and the mechanisms underlying them remain a matter of debate. If prosocial responding in adults is driven by understanding others' emotions and desires in combination with a motivation to act on others' behalf (Batson, Ahmad, Powell, & Stocks, 2008), how can we explain prosocial acts in very young children who have still rudimentary social-cognitive abilities and emergent other-oriented motivational systems?

Current theory and research provide different, sometimes contrasting, views about contributors to the early development of prosocial behavior. Some have proposed that infants' interest in people and their actions combined with basic affiliative and imitative tendencies lie at the root of their initial prosocial responses (Grusec, 2006; Hay & Cook, 2007; Rheingold, 1982). Others maintain that the critical contributor to early prosocial behavior is the developing ability to differentiate another's internal states from one's own and to relate one's own emotions and needs to another's in order to act on the other's behalf (Bischof-Kohler, 1991; Mascolo & Fischer, 2007; Moore, 2007; Zahn-Waxler & Radke-Yarrow, 1990). Still others argue for an innate biological substrate for empathy and altruism in infants (Hoffman, 1975; Tomasello, 2008; Zahn-Waxler, Robinson, & Emde, 1992), in part because some prosocial behaviors appear to be uniquely human and emerge before formal socialization begins, suggesting that children may start out being naturally altruistic (Silk et al., 2005; Warneken & Tomasello, 2009).

This research was supported in part by grants from the National Institute of Child Health and Human Development, HD043971 and HD055283, to the last author. Portions of this research were presented at the International Conference on Infant Studies. We thank all the children and parents who volunteered their time to participate in this study. Special thanks to Ranita Anderson, Catie Henderson, Maryam Khatami, Liz Posti, Stephanie Sivers, Hilarie Stern, and Emily Yarrison for assistance with recruitment, data collection, and coding.

These different theoretical perspectives place different emphasis on the social-cognitive and motivational components of early prosocial responding. In addition, the *nature* of each of these components may differ as a function of age, giving the same behavior (e.g., bringing something to someone) different meaning depending on the child's social-cognitive and motivational competences. Prosocial behavior of an infant or toddler may be driven by different forms of social understanding than the same behavior exhibited by an older child or an adult. For example, infants may first interpret others' emotional expressions and behaviors as being about the objects to which they are directed rather than about the other person's mental states or psychological attitudes (Gergely, Egyed, & Kiraly, 2007). Correspondingly, young children's social responses may be based on less sophisticated inferences about the minds of others, or on even simpler mechanisms such as reading behavioral cues or understanding the contingencies between behavior and its outcomes (e.g., Moore & Povinelli, 2007; Perner & Ruffman, 2005).

We can ask, then, to what extent do 1-year-olds who help their parents empty the dishwasher, wash the dog, sweep up spilled cereal, and the like, do so out of caring concern for the parent's needs as opposed to being interested in the action itself, enjoying the social exchange, or even relishing the praise that often follows? What inferences do toddlers make about parents' desires, feelings, or needs when they help? When are they able to be altruistic, giving up something of value knowingly and voluntarily? One way to clarify such questions is to compare children's performance in situations that require the same basic behavioral competence but that differ with respect to their underlying understanding and motivation.

During the 2nd year of life, social understanding becomes increasingly "mentalistic" (Flavell, 1999), and many aspects of social behavior are transformed (see Brownell & Kopp, 2007), making this period particularly relevant for investigating such issues. In the current study, we examined helping behavior in 1- and 2-year-olds, a period when children's social understanding rapidly develops—and when prosocial responding first emerges. We presented toddlers with tasks that were similar behaviorally but differed in their specific social-cognitive and motivational demands. Our premise was that if children behave prosocially in versions without the relevant demand and fail to do so in corresponding versions with that demand, we would be able to isolate specific components of prosocial responding that are and are not yet in place at a given age. The factors that we experimentally manipulated were the nature of the inference that the child had to make about the other's need, the cost of helping to the child, and the amount of communicative support available to the child about the other's need and how to help. By contrasting the conditions under which 1-year-olds help with those under which 2-year-olds help, we aimed to shed light on developmental changes in the sources of early prosocial behavior.

Instrumental Versus Empathic Helping

The 2nd year of life is witness to major developmental change in prosocial behavior. Instrumental helping, or assisting another in achieving an action-based goal such as searching for or getting something out of reach, appears by 12–14 months of age (Liszkowski et al., 2006; Warneken & Tomasello, 2007), presumably deriving from early-developing understanding of goals and goal-directed behaviors (Woodward, 1998). The ability to respond prosocially to others' emotional distress emerges somewhat later, with a significant increase between 18 and 24 months of age in expressions of concern and comforting behavior toward others in pain (Zahn-Waxler, Radke-Yarrow, et al., 1992). This is associated with the development of objective self-awareness and likely to be a function of children's corresponding understanding of others as psychological agents (Hoffman, 2007; Moore, 2006, 2007; Zahn-Waxler, Radke-Yarrow, et al., 1992).

In addition to growing social understanding, the motivational mechanisms involved in early prosocial behavior may undergo developmental change during toddlerhood. Not all the possible motivations for behaving prosocially are other oriented, perhaps especially in young children. For example, in a study by Rheingold (1982), 18-month-olds participated at high rates in "helping" their parents to set a table, sweep up bits of paper, put cards in a box, and so forth. However, the fact that children in the study often initiated an action even before the adult expressed a need or started to act points to the possibility that they may have simply enjoyed participating in social activities alongside adults, were seeking adults' approval, or found the activities themselves interesting or fun, rather than being concerned about the other's well-being. Even in older children and adults, prosocial behavior can be motivated by self-oriented concerns such as a desire for social approval, concrete rewards, or reciprocal prosocial responding (Eisenberg, 2005). It is possible, then, that very early instances of *instrumental helping* are motivated as much by more rudimentary forms of self-interest, or interest in the persons, objects, or actions involved, as by compassionate concern for others. *Empathic helping*, that is, prosocial responding grounded in other-oriented concern, may develop later along with children's growing understanding of others as independent agents with internal states that differ from children's own (Hoffman, 2007; Mascolo & Fischer, 2007).

One purpose of the current study was to test this hypothesis by extending previous work on toddlers' instrumental helping (Rheingold, 1982; Warneken & Tomasello, 2006) to include empathic helping and to test 2-year-olds as well as 1-year-olds. We built on the existing experimental work by Warneken and Tomasello (2006), in which they demonstrated that 1-year-old children readily help an adult instrumentally with a variety of goal-directed actions and do so more often than in comparable control tasks in which helping is not necessary. In the current study, we contrasted instrumental and empathic helping by presenting 18- and 30-month-old children with tasks in which they could help an adult by offering her an object that she needed, for example, bringing her an out-of-reach toy so she could continue an interrupted game, or giving her a blanket to make her warm. We expected that children would be more likely to demonstrate prosocial behavior when it involved helping someone to complete an interrupted action (instrumental helping) than when helping was based on inferring and alleviating another's negative internal state (empathic helping). We also expected that this difference would be greater for 18-month-olds than for 30-month-olds, who are more skilled at inferring others' internal states (Lewis & Carpendale, 2002; Repacholi & Gopnik, 1997) as well as more concerned about them (Radke-Yarrow, 1986; Spinrad & Stifter, 2006; Zahn-Waxler, Radke-Yarrow, et al., 1992).

Altruistic Helping

Prosocial behavior, even when it is other oriented, may not always be genuinely altruistic. A child can give a hug to a distressed friend or bring Mom her mittens, which may improve the other person's well-being without diminishing the child's own well-being; in fact, such behaviors are often rewarded, for example, by a reciprocal hug or praise. To what extent are these behaviors altruistic? The answer to this question depends in part on how we define altruism. Scholars from different disciplines provide different definitions: In evolutionary biology, a behavior is deemed altruistic only when it raises the expected reproductive success of the recipient at the expense of the reproductive success of the donor (Kitcher, 1998), whereas psychologists generally use less strict terms, although their definitions, too, range in the degree of self-sacrifice required. Grusec, Davidov, and Lundell (2002) characterize altruistic behavior as intentional assistance to others that comes at a cost to the donor. Piliavin and Charng (1990) argue that altruistic behavior must be performed without expecting any external reward. The general agreement seems to be that for an act to be considered altruistic, the recipient's well-being must be the donor's ultimate goal (Batson et al., 2008; Foster, Wenseleers, & Ratnieks, 2006); that is, the recipient's benefit must be perceived as an end in itself, not as a means to the achievement of some of the donor's other goals (Kitcher, 1998). When does the ability to act on behalf of others—without considering one's own interests and potentially at a cost to oneself—first emerge?

Young children may behave prosocially before they behave altruistically. Toddlers are notoriously poor at sharing their possessions, but with the rapid development of self- and other-understanding over the 2nd year their rates of sharing, helping and cooperating increase (Hay, 2006; Hay & Cook, 2007; Smiley, 2001). However, it is possible that costly helping, especially when it involves sacrificing one's own possessions, may become more difficult, not less so, as children better understand ownership and the costs of sharing in the 3rd year of life (Fasig, 2000; Hay, Caplan, Castle, & Stimson, 1991; Imbens-Bailey & Pan, 1998). Thus, children's motivation to behave altruistically, subordinating their own interests to those of others, may instead decrease with advances in social understanding.

Although toddlers may be motivated to help others, few empirical studies have directly tested their willingness to help as a function of whether self-sacrifice is required or not (cf. Warneken & Tomasello, 2008). Thus, the second purpose of the current study was to examine children's helping behavior in situations that involved someone else's belongings in comparison to situations that required the children to give up their own belongings altruistically (e.g., giving their own blanket brought from home to an adult who was feeling cold). Prior research has shown that children will sometimes give up something in their possession (e.g., Vaish, Carpenter, & Tomasello, 2009), or willingly stop playing an interesting game (Warneken & Tomasello, 2008) to help an adult in distress. Giving up something of one's own, especially an object from home, is still a different type of cost, and arguably a more stringent test of altruistic motivation insofar as it carries greater personal significance and value (Blake & Rand, 2010). We expected children at both 18 and 30 months of age to help more often and more quickly in tasks that did not require them to sacrifice their own belongings. We also expected older children to be more altruistically motivated, hence to help more readily than younger children even in the face of a personal sacrifice; however, we entertained the possibility suggested by Hay et al. (1991) that older children could be less willing to give up something of their own.

The Role of Adult Communication in Early Prosocial Behavior

Prosocial behavior develops within the crucible of social interaction. It is through dyadic interaction with adults that young children's social understanding and responding are socialized and shaped (Dunn, 1988; Grusec, 2006). Notably, in most of the studies reviewed earlier adults used a variety of ostensive cues to communicate their emotions, intentions, or desires explicitly, often with exaggeration to make them salient and clear. Such communication may serve to scaffold children's attention to, interest in, and inferences about others' internal states and the characteristics of the objects or events toward which adults behave. Some researchers have found that infants require the supportive, mutual engagement of an adult to recognize what the adult is attending to (Moll, Carpenter, & Tomasello, 2007) and that infants' ability to interpret others' behavior and to understand what another person feels, needs, or wants may initially depend on adults' scaffolding and communicative support (Carpendale & Lewis, 2004; Ruffman, Slade, Devitt, & Crowe, 2006; Tomasello, 1995). In a recent study of sharing in toddlers, it was shown that 24-month-olds were able to infer and act on an adult's desire for a snack from the adult's explicit verbal expressions of desire, but not when the adult was silent (Brownell, Svetlova, & Nichols, 2009). Prosocial behavior may therefore be more likely when adult communications make the other's needs, desires, and emotions more apparent and reduce the need for complex inferences about others' internal states.

The third purpose of our study was to examine how adults' communications support young children's prosocial responding. To this end, we systematically manipulated the expressive cues provided by the adult during the helping tasks. For each task, the adult made her need and how to help progressively more explicit with a fixed sequence of specific gestural, vocal, and verbal cues, for example, first simply vocalizing "Brrrr!" with shivering and shaking, then reaching toward an out-of-reach blanket with gaze alternation between the child and the blanket. The cues culminated in a direct request for a particular object (e.g., "Can you bring me the blanket?"). Children were assigned a helping score based on when in the sequence of cues they helped the adult. If they helped spontaneously without any supportive cueing from the adult, they received the maximum score, whereas they received the minimum score if they helped only when specifically requested to do so. We expected that 18-month-olds would receive lower scores than 30-month-olds, that is, that younger children's helping responses would depend on more explicit and direct communications about the adult's needs. We also expected that the communicative support from adults would become more necessary as the complexity of the inference about the other's internal states increased; thus, we expected that children would receive higher scores for instrumental helping than for empathic helping and higher scores for empathic helping than for altruistic helping.

Overview of Design

To examine the roles of developing social understanding, prosocial motivation, and adult communicative support in early prosocial behavior, we presented each child with nine tasks in which an adult needed help and the child could provide it by bringing a nearby object that the adult could not reach. We contrasted children's *instrumental* helping behavior in an "action" condition, in which the adult needed an object to complete a goal-directed action, with their *empathic* helping in an "emotion" condition, in which the adult needed an object to alleviate a negative emotion. Even though the target behavior was identical in the two conditions, we expected children to help more readily in the action condition than in the emotion condition. Because understanding of goal-directed behavior developmentally precedes the ability to infer and represent others' internal emotional states, we expected greater difference between the two conditions among 18-month-olds than among 30-month-olds. We also contrasted children's instrumental and empathic helping with *altruistic* helping in which they had to give up something of their own to help the adult (the "altruism" condition). We expected children to help more readily when they did not have to sacrifice their own belongings. Finally, in each helping task we manipulated the adult's communications about her need and what could be done to help her. We expected younger children to require more communicative cues to support their helping behavior, especially in the emotion and the altruism conditions.

Method

Participants

Thirty-two 18-month-olds (*M* = 18.46 months, *SD* = 0.48; 15 boys and 17 girls) and thirty-three 30-month-olds (*M* = 30.32 months, *SD* = 0.68; 18 boys and 15 girls) participated in the study. Seven additional children were tested but their data were not usable because of procedural error or the child's refusal to participate in any of the tasks. Participants came from working- and middle-class families from a medium-sized city and surrounding suburbs. Seventy-eight percent were Caucasian, 11% were Asian, 7% were African American, and 4% were Hispanic. All children were walking, talking, and were healthy and developing normally by parent report.

General Procedure

Children arrived to a laboratory playroom with their caregivers who remained in the room completing questionnaires and were asked not to encourage, reward, or comment on the child's behavior. Testing was conducted by a female experimenter (E) with the help of a female assistant (AE). The session began with a warm-up and familiarization period during which E and AE played with the child for several minutes to ensure that the child was comfortable approaching and interacting with both of them. During warm-up, E and AE also demonstrated various objects that were later used during testing, to be sure that children understood their use and to control for possible differential exposure prior to the study. Specifically, AE came in with messy hair and showed how to fix it with a hairclip, also giving the child a chance to play with the hairclip. She then gave a small stuffed toy with an attached hairclip to the child and told the child that both the toy and the hairclip were for him or her to take home (the toy accompanied the hairclip to make the gift equally interesting for girls and boys). AE also showed the child how a blanket could be wrapped around her shoulders to make her feel warm. E showed her teddy bear to the child, saying that it was her special toy that made her feel happy. Parents had been asked to bring the child's own blanket and favorite toy from home; thus, together with the newly acquired hairclip, there were three objects belonging to the child. Before the experiment started, AE placed all the objects behind a curtain; the objects were later retrieved as relevant in each testing episode. The experimental session was structured so that testing episodes were alternated with free-play episodes. The session was video recorded through a one-way mirror for later coding.

Nine helping tasks (one trial per task) were presented, in which E demonstrated difficulty or distress which could be alleviated by giving her a particular object. Prior to each trial, the target object (the one that E needed) and two distracter objects were placed on a tray out of E's reach, but within the child's reach. The distracter objects served as targets in other trials. On each trial, E provided up to eight progressively more explicit cues as to her need or emotion and what could help or comfort her. All tasks were administered within subjects. To control for possible fatigue or familiarization effects, the order of tasks was counterbalanced using a modified Latin square design, with a total of nine possible orders; no two tasks from the same condition ever occurred in a row. Approximately equal numbers of children received each order.

Conditions and Tasks

The nature of the inference that children had to make about E's need and the degree of sacrifice they had to make were manipulated via three conditions (action, emotion, and altruism), with three trials per condition. In the action condition, the child had to infer E's action-related goal (three trials); in the emotion condition, the child had to infer E's emotion or internal state (three trials). In both of these conditions, the needed object belonged to E. The altruism condition (three trials) was identical to the emotion condition except that the child had to give up something of his or her own to help or comfort E, thus requiring a sacrifice on the child's part to alleviate E's distress.

More specifically, in the action condition, E had difficulty completing three different goal-oriented actions involving objects that were out of reach because they had been dropped or misplaced; the child could help by bringing the object necessary to complete each action. This condition emphasized the interrupted action, not E's internal state. In the emotion and altruism conditions, E demonstrated three different negative internal states (sadness, cold, and frustration); the child again could help by bringing specific objects to E. These conditions emphasized the adult's distress and the child's help served to alleviate the distress instead of completing an interrupted action.

The three trials in each condition were equated across conditions to ensure that the tasks were parallel, that is, involved the same behaviors and objects in each condition. The three task types in each condition were: (a) need for a clip for attaching something, (b) need for a blanket or cloth for wrapping, and (c) need for a toy for playing or comforting. Thus, the tasks were similar across conditions in terms of the target object needed and the specific helping behavior required, but they had different social-cognitive and motivational demands depending on the condition. For example, a clip could be handed to the experimenter to help her complete the action of clipping cloths to a line (action condition) or to alleviate her feeling of frustration with her messy hair (emotion and altruism conditions), with the clip belonging to the child in the altruism condition. Hence, the required helping behavior and the required object were identical in the three conditions (e.g., handing a clip to E), but helping in each condition required a different inference about the need of the recipient and/or a different motivation. Whereas in the action condition helping was based on understanding another person's goal and motivated by wanting to facilitate an interrupted goal-directed action, in the emotion condition it required understanding another person's internal state and wanting to alter that state, with an additional altruistic motivation in the altruism condition.

Description of Tasks

Action Condition

Clipping task (adapted from Warneken & Tomasello, 2006). E is clipping square pieces of fabric to a clothesline and drops a clothespin out of reach. Child's target behavior: Hand the clothespin to E.

Wrapping task. E is wrapping wooden blocks in square pieces of fabric (sitting behind a small table), and runs out of wrappers on the final block. An additional wrapper is available on the tray which can be reached by the child but not by E. Child's target behavior: Hand the wrapper to E.

Toy task. E is playing with a toy car together with a toy driver that fits in the car, then absentmindedly places the car on the tray near the child to play another short game with the child. She then reseats herself behind the table and away from the tray picks up the driver to start playing again, but has no car. Child's target behavior: Hand the car to E.

Emotion Condition

Clipping task. AE places the hairclip on the tray near the child and leaves. E enters the room with her hair in her eyes, sits on the floor out of reach of the tray, and demonstrates her frustration and distress with actions, moans, and sighs as she tries unsuccessfully to move her messy hair away from her face. Child's target behavior: Hand the hairclip to E.

Wrapping task. E shows her blanket to the child, reminding the child that it makes her warm. She then places the blanket on the tray near the child as she begins a game with the child, moves out of reach of the tray, and sits on the floor. E suddenly becomes cold, shivering, rubbing her arms, and saying "Brrrr" with a distressed expression on her face. Child's target behavior: Hand the blanket to E.

Toy task. E shows her teddy bear to the child, reminding the child that it is her favorite toy and that it makes her happy. She then places the teddy bear on the tray near the child and moves out of reach of the tray. AE enters and whispers something to E, who immediately becomes sad, sighing and sobbing as she sits on the floor. Child's target behavior: Hand the teddy to E.

Altruism Condition

Clipping task. AE places the child's hairclip (given to the child during the warm-up and attached to a stuffed toy) on the tray near the child and leaves. E enters the room with her hair in her eyes, sits on the floor out of reach of the tray, and demonstrates frustration with actions, moans, and sighs as she tries unsuccessfully to move her messy hair away from her face. Child's target behavior: Hand the child's *own* hairclip to E.

Wrapping task. E places the child's blanket, brought from home, on the tray near the child; she points it out and talks about it with the child, mentioning that it must be warm. She then begins a game with the child, moving out of reach of the tray, and sits on the floor. E suddenly becomes cold, shivering, rubbing her arms, and saying

"Brrrr" while looking distressed. Child's target behavior: Hand the child's *own* blanket to E.

Toy task. E places the child's favorite toy, brought from home, on the tray near the child; she points it out and talks about it with the child, saying that it looks very special and must make the child happy. E then moves out of reach of the tray and suddenly receives a call on her cell phone, which makes her sad, and she begins to sigh and sob. Child's target behavior: Hand the child's *own* toy to E.

Communicative Cues

On each trial, the experimenter provided up to eight progressively more explicit cues about her need or emotion and what the child could do to help or comfort her. The cues and their order of presentation were the same across trials. The first two cues communicated the experimenter's *state* gesturally, then verbally (e.g., shivering; saying "I'm cold"); the third cue stated the *general need* (e.g., "I need something to make me warm"); the fourth cue drew the child's attention to the *target object* by labeling it (e.g., "a blanket!"); and the rest of the cues informed the child with increasing specificity about *how to help or comfort* the experimenter, with the final cue giving a very *specific instruction* (e.g., "Can you bring me the blanket?"). Table 1 displays the order of presentation and description of each of the eight cues.

Each cue was presented for 5–7 s. Once the child handed the target object to the experimenter, she stopped providing cues. If the child brought one of the distracter objects first, E took it from the child with a neutral facial expression and continued to provide cues until the child brought the target object. If the child did not bring the target object by the last cue, the experimenter got up and retrieved it herself without reaction or comment and then proceeded to the next play episode. To reduce the possibility of simple compliance or attempts to seek adult approval, the experimenter did not thank, praise, or reward the child when the child brought the object, but instead neutrally described the result (e.g., "Now I can clip," "Now I feel warm").

Measures

Children's responses to each helping task were coded from video records. For each task, the child received a "target helping score," corresponding to the specific cue in the sequence of eight communicative cues when the child brought the target object to the experimenter (see Table 1 for the scores assigned to each cue). Higher scores represent more skilled responding, that is, earlier responses in the cue sequence, requiring less social and communicative support. A child who did not bring the target object by the final cue on a given task received a score of 0 for that task. As an indicator of their general propensity to help, children were also coded for whether they brought any object, either target or distracter, at any cue level, for each task (coded 0 or 1). Video records were coded by two trained research assistants blind to the study's hypotheses. Reliability was calculated on 21% of the data, resulting in a weighted $k = .89$.

Results

Preliminary analyses were conducted to check for gender, task, and task order effects. No differences

Table 1
Communicative Cues and Corresponding Helping Scores

Order of presentation	Description	Helping score assigned
1	Facial/bodily/vocal expression of general need (e.g., hands up, looking around, "hmmm") or internal state (e.g., shivering with cold, rubbing and hugging oneself to get warm, "brrrr")	8
2	Naming the interrupted action (e.g., "I can't clip!") or internal state (e.g., "I am sad")	7
3	Verbal expression of a general need for an object (e.g., "I need something to clip with" or "I need something to make me feel warm")	6
4	Naming the specific object that would meet the need (e.g., "A clothespin!" or "A blanket!")	5
5	Alternating gaze between the object and the child, as a nonverbal request to get the object	4
6	Reach and gesture toward the object, as a more explicit request to get the object	3
7	General verbal request for help ("Can you help me?")	2
8	Specific verbal request (e.g., "Can you bring me the blanket?")	1

were found for gender or task order on any outcome variable, so all subsequent analyses were conducted on data collapsed over gender and order. Overall, task effects varied unsystematically across conditions, suggesting that no particular type of task was more or less familiar or difficult than others; in particular, tasks did not differ in difficulty within the emotion condition. Analyses also showed that task did not interact with order or gender to affect performance, nor did order interact with condition.

Two sets of substantive analyses are presented. The first set addressed general questions about whether 30-month-olds helped more often across contexts and manipulations than did 18-month-olds, and whether their helping was more specific and appropriate. The second set of analyses examined age and condition differences in how readily children helped and how much communicative support they needed, using the target helping score as the dependent measure.

General Propensity to Help and Appropriateness of Help

To examine age differences in children's general propensity to help the experimenter, we analyzed the number of times children brought any object (either the target or the distracter object) across all nine trials, regardless of the cue level at which they did so. All children exhibited some degree of helping toward the experimenter. Among 18-month-olds, every child helped by bringing some object on at least two of the nine trials, and 44% helped on all nine. Among 30-month-olds, every child helped on at least six of the nine trials, and 84% helped on all nine. An independent-samples t test on the mean number of helping responses yielded a significant age difference, with 30-month-olds helping more often ($M = 8.74$, $SD = 0.68$) than 18-month-olds ($M = 7.40$, $SD = 1.88$), $t(61) = 3.72$, $p < .001$. Thus, older children were more inclined to help overall, but even younger children helped, on average, on more than seven of the nine opportunities. It is important to note, however, that this includes instances of directed or instructed helping when the experimenter specifically requested the target object by name (e.g., "Can you bring me the blanket?"), as well as instances of helping by bringing the distracter object, that is, without discriminating whether the object was the one that the experimenter actually needed.

To examine children's ability to help appropriately by bringing the specific object that the adult needed, we conducted a two-way repeated measures analysis of variance (ANOVA) with age group (18 and 30 months) as the between-subjects factor, and condition (action, emotion, altruism) as the within-subjects factor, on the mean number of times children brought the target object, regardless of cue level (see Figure 1). Across conditions, older children brought the target object significantly more often ($M = 2.87$ out of three trials per condition, $SD = 0.38$) than did younger children ($M = 2.31$, $SD = 0.51$), $F(1, 61) = 14.73$, $p < .001$. There was also a significant effect of condition, $F(2, 122) = 19.16$, $p < .001$. Post hoc pairwise comparisons (LSD) revealed that children of both ages brought the target significantly more often in the action condition ($M = 2.84$, $SD = 0.41$) than in the emotion condition ($M = 2.69$, $SD = 0.67$), $p = .03$, and significantly more often in the emotion condition than in the altruism condition ($M = 2.24$, $SD = 0.98$), $p = .001$. The interaction was not significant. Thus, collapsing across cue levels, 30-month-olds more often helped and more often helped appropriately by bringing the object that the experimenter actually needed. All children tended to exhibit more appropriate helping in the action condition than in the emotion and the altruism conditions.

How Readily Children Helped as a Function of Age and Helping Condition

To determine whether there were age or condition differences in how readily children helped, that is, how much communicative support they needed to help appropriately, a two-way repeated measures ANOVA, with age group (18 and 30 months) as the between-subjects factor and condition (action, emotion, altruism) as the within-subjects factor, was conducted on the target helping scores. Higher scores corresponded to earlier, more

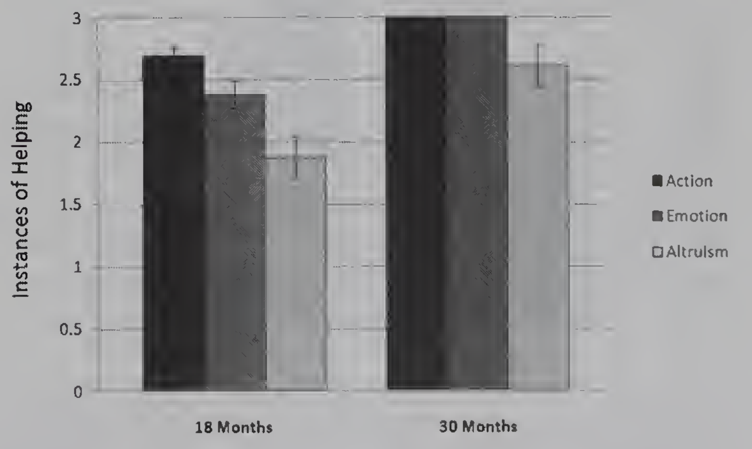

Figure 1. Mean number of times (± *SE*) children helped by age and condition (out of three possible instances per condition).

skilled helping with less communicative support from the adult. Nonparametric analyses for ordinal data produced identical results.

A significant difference between age groups was found, $F(1, 61) = 61.99$, $p < .001$. Across conditions, 30-month-olds helped more readily, that is, at earlier cue levels ($M = 5.41$, $SD = 1.14$), than did 18-month-olds ($M = 3.25$, $SD = 1.07$). There was also a significant effect of condition, $F(2, 122) = 68.04$, $p < .001$. Post hoc comparisons (LSD) revealed that across ages, children helped more readily in the action condition ($M = 5.62$, $SD = 1.70$) than in the emotion condition ($M = 4.28$, $SD = 2.01$), $p < .001$, and in the emotion condition than the altruism condition ($M = 3.09$, $SD = 1.77$), $p < .01$.

These main effects were qualified by a significant interaction between age and condition, $F(2, 122) = 5.91$, $p < .001$ (see Figure 2). Younger children needed significantly less communicative support to help in the action condition ($M = 4.64$, $SD = 1.75$) than in either the emotion condition ($M = 2.79$, $SD = 1.55$), $t(31) = 6.26$, $p < .001$, or the altruism condition ($M = 2.33$, $SD = 1.44$), $t(31) = 7.08$, $p < .001$, which did not differ from each other, $t(31) = 1.75$, *ns*. Older children, on the other hand, helped more readily in the action condition ($M = 6.61$, $SD = 0.88$) than in the emotion condition ($M = 5.77$, $SD = 1.26$), $t(30) = 3.21$, $p = .003$, and more readily in the emotion condition than in the altruism condition ($M = 3.85$, $SD = 1.76$), $t(30) = 5.49$, $p < .001$.

As a more stringent test of children's ability to help, we conducted nonparametric tests on the number of children who helped immediately by bringing the target object after the initial communicative cue from the experimenter (i.e., nonverbal expression of need). Among 18-month-old children, 44% helped the adult immediately and appropriately on one or more of the tasks in the action condition (out of three); that is, they brought the target object when the adult first registered her difficulty with facial expression, vocalization, and/or posture. In the emotion condition, this dropped to 13%, and in the altruism condition only 6% of 18-month-olds helped the adult immediately at least once. Among 30-month-olds, 87% helped immediately one or more times in the action condition, as did 64% in the emotion condition, but only 18% helped immediately at least once in the altruism condition. Age differences in the number of children who helped immediately one or more times were significant for the action condition, $\chi^2 = 20.30$, $p < .001$, and the emotion condition, $\chi^2 = 18.30$, $p < .001$, but not for the altruism condition, $\chi^2 = 2.43$, *ns*.

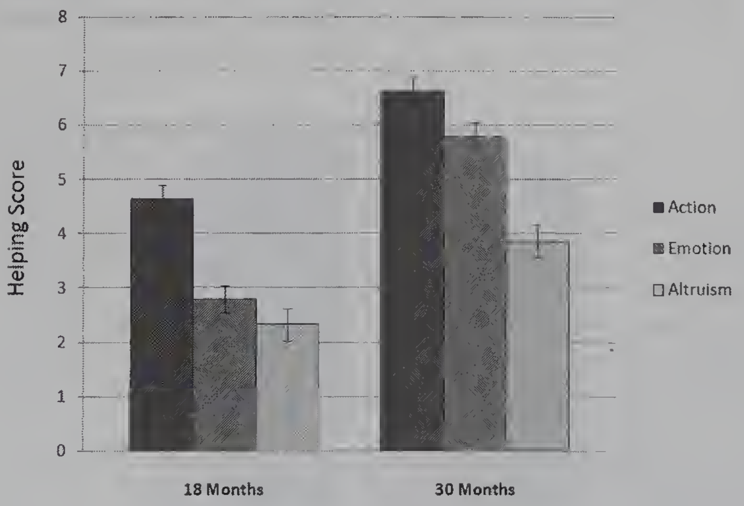

Figure 2. Mean target helping scores (± *SE*) by age and condition.
Note. Higher scores indicate earlier helping with less communicative support.

Discussion

In this study, we examined early developments in young children's ability to help others in need. Our data confirmed previously reported findings that toddlers as young as 18 months are able to help adults instrumentally, and that the propensity to respond prosocially grows significantly between 18 and 30 months of age. The particular novelty of this study was in the manipulation of factors that could underlie helping behaviors at each of the examined ages, specifically, the nature of the inference that the child had to make about the other's need, the cost of helping to the child, and the amount of communicative support provided by the adult in need of help. By varying these factors we aimed to clarify possible social-cognitive and motivational mechanisms that support early prosocial behavior and its development in the 2nd and 3rd years of life. Helping an adult instrumentally to complete an interrupted action-related goal was significantly easier than empathic helping to alleviate an adult's emotional distress, particularly for 18-month-olds. Helping was also easier when it did not require children to give up something that belonged to them, at both 18 and 30 months. We also found that 18-month-olds' helping required significantly greater communicative support and scaffolding from an adult than that of 30-month-olds, whose prosocial behavior was more autonomous and demonstrated greater social understanding.

Age-Related Differences in Helping and Requisite Adult Communication

Prosocial responses emerge early in the 2nd year of life (Rheingold, 1982; Warneken & Tomasello, 2006, 2007) and increase over childhood in concert with growing self-other differentiation and social understanding (Bischof-Kohler, 1991; Brownell & Carriger, 1990; Moore, 2006; Zahn-Waxler, Radke-Yarrow, et al., 1992). However, prosocial responses among 1-year-olds are infrequent, occur more reliably for familiar situations and emotion contexts (e.g., pain; Zahn-Waxler, Radke-Yarrow, et al., 1992) than for less familiar situations (e.g., sadness, fatigue; Sigman, Kasari, Kwon, & Yirmiya, 1992), and can be increased by explicit requests for assistance (Rheingold, 1982; Spinrad & Stifter, 2006). Even at age 2, prosocial behavior remains irregular and does not occur reliably across trials or tasks (Demetriou & Hay, 2004; Hay, 2006).

In the current study, both 18- and 30-month-old children helped the experimenter on the majority of trials. However, these apparently high helping rates included instances in which the adult explicitly requested help from the child and specified what was needed. Furthermore, when we consider the particular circumstances under which 18-month-olds helped, it becomes clear that their performance was mostly accounted for by helping in the action-related tasks, in which the experimenter had difficulty completing a goal-directed action. For emotion-related tasks, where children had to infer the adult's internal state and intervene to alleviate it, 18-month-olds were unlikely to help unless they received substantial communicative support and scaffolding from the adult. On average, the younger group tended to respond after the adult had expressed her internal state or need in different ways and had named the target object. Thirty-month-olds exceeded 18-month-olds on all measures of prosocial behavior in all conditions. As predicted, not only did older children help more frequently, but they also required less communicative support from the adult, tending to help before the adult had named the object that she needed. Thus, 18-month-olds are most able to respond prosocially in situationally obvious, goal-oriented helping situations when they are supported by very clear communications about what the other person needs and what can be done to mitigate the need. By 30 months of age, children's greater ability to infer another's needs from more general information and more subtle cues permits them to recognize another's need for help more easily and to rely less on the adult for this information.

One implication of these findings is that very early prosocial responding depends on social and communicative support from others about their needs and how the child can help. Several investigators of early social-cognitive development, starting with Vygotsky (1978), have emphasized the essential role of partner support when children first acquire new knowledge and skills. In a classic study of 6- to 18-month-old infants and their mothers, Bakeman and Adamson (1984) showed that new forms of social engagement first appeared embedded in and supported by the social interaction context. In their study, mothers initially acted in ways that scaffolded their infants' performance before infants were capable of such performance on their own; with age and repeated exposure, infants themselves exhibited more skilled and autonomous forms of engagement. We can speculate that new forms of social understanding and the corresponding prosocial responses are socialized in a similar way. In the current study, tasks with more challenging social-cognitive demands required more prolonged, specific, and explicit communication; with age, children's need for such communication decreased. While human infants may have a natural predisposition to be prosocial early in development (Warneken & Tomasello, 2009), social and communicative support from adults appears to be important in scaffolding young children's understanding of when and how to enact prosocial responses.

Social Understanding: Actions Versus Emotions

In line with our expectations, instrumental, action-related tasks elicited the most robust helping responses and required the least scaffolding from an adult. Even for 30-month-olds helping in the action condition was significantly easier than in the other two conditions. This is consistent with existing research on development of early social understanding that has shown that by the middle of the 2nd year of life children are able to understand other people's goals and intentions (Meltzoff, 1995; Tomasello, Carpenter, Call, Behne, & Moll, 2005). Even though emotion understanding also undergoes important developments in this period (Eisenberg, 2005; Mascolo & Fischer, 2007), enabling some forms of empathy (Spinrad & Stifter, 2006; Zahn-Waxler, Radke-Yarrow, et al., 1992), empathic helping appears to be more complex than helping with action-related tasks. Unlike helping based on predicting action–effect outcomes in observable actions (Csibra & Gergely, 2007), helping in response to others' emotions requires an additional step in social-cognitive processing, as inferring the goal in this case follows from inferring someone's internal state. Furthermore, emotion-related tasks can lead to personal distress in young children via emotion contagion, perhaps especially when others are in pain or evident distress. This requires young children both to differentiate their own distress from the other's distress and to regulate their own distress if they are to exhibit empathic helping based on other-oriented concern or sympathy rather than based on the wish to reduce their own personal distress (Eisenberg, 2005; Hoffman, 1975). As a result, both cognitive and affective demands are greater in empathic helping compared to instrumental, action-related helping. The ability to understand and assist others with goal-directed actions may represent the first step toward this more complex social understanding and associated prosocial responses.

Together with other recent research, the current study points to an important transition from instrumental helping to empathic helping late in the 2nd year of life and early in the 3rd. Warneken and Tomasello (2007) demonstrated that 14-month-olds are able to help adults in only the most straightforward instrumental tasks, those involving reaching. Between 18 and 24 months of age, toddlers are able to help in a wider array of instrumental tasks that include difficulties with tools, obstacles, means–end relationships and the like, suggesting more advanced understanding of others' action-related goals (Warneken & Tomasello, 2006). In the current study, by contrasting instrumental and empathic helping, we discovered that empathic helping is quite limited at 18 months but relatively skilled by 30 months of age. The developmental picture suggested by integrating these findings is that by 14 months of age, toddlers are able to help others with simple, goal-directed actions; by 18–24 months they can help in action-related situations that are more demanding cognitively but still relatively transparent with respect to another's goals and needs; and by 30 months of age, they are able to help in emotion-related situations requiring more complex inferences about others' needs based on inferring others' feelings and internal states.

Altruistic Motivation: Cost Versus No Cost

The altruism condition, in which helping required the child to give his or her own possession to the experimenter, was included in the design to examine the motivational component of early prosocial behavior. Recall that the only difference between the altruism and emotion conditions was whether the objects needed by the adult were the child's own or the adult's. As the two conditions were otherwise identical, any differences in helping must have been due to affective or motivational, rather than cognitive, mechanisms. As expected, the altruism condition was the most difficult for both ages. Interestingly, however, 18-month-olds' behavior did not differ significantly for the emotion condition versus the altruism condition. Indeed, their helping scores were near the floor in both. In other words, whether a sacrifice was involved or not, 18-month-olds had an equivalently difficult time understanding the adult's emotion-related needs and required substantial input from the adult to come up with a helping response. Among 30-month-olds, however, both the rates of helping and how early in the cue sequence children responded differed significantly between the altruism and emotion conditions, even though the social-cognitive demands were identical. Although 30-month-olds knew about the adult's need and how to help in the emotion tasks, they were less willing to provide costly help in the altruism tasks. For the younger group, therefore, the challenge seemed to be in disentangling the complex social understanding demands of the emotion-related tasks, whereas the older group had the most difficulty with overcoming their possessiveness and giving up something of value.

These findings suggest that very young children exhibit a general prosocial motivation, readily providing instrumental help to an adult when the amount of information about what is needed corresponds to their level of social understanding. Yet, when the demands of the task involve a sacrifice—giving their own possession to alleviate another's distress—this motivation is reduced. Grusec et al. (2002), among others, define prosocial behavior as any intentional action that produces a positive outcome for the recipient, whereas altruism implies that assistance to others comes at some cost to the donor. The fact that instances of costly helping in the current study were quite low and often occurred in response to an adult's direct and explicit request suggests that toddlers' helping responses were unlikely to be genuinely altruistic. Altruistic motivation appears to be a later developing phenomenon, which may build upon the more basic prosocial motivation emerging and developing in toddlerhood.

Several limitations of this study are worth noting. First, the contrast between the action condition and emotion condition was not as strong as it could be in some respects, but in other respects may have been too distinct. For example, the emotion of frustration is in part a response to a blocked goal (Witherington, Campos, & Hertenstein, 2001) and as operationalized in the current study also has an action component (e.g., moving one's hair away from one's face). Clearer distinctions between these conditions might produce clearer developmental differences between instrumental and empathic helping. Another limitation is the absence of an action version of the altruism condition, thereby constraining our examination of altruistic responding to empathy-related helping situations. Future research could address whether altruism emerges earlier in instrumental helping than in empathy-related helping contexts. Finally, perhaps some children failed to help because they chose not to help, believing that adults bear responsibility for helping others (Caplan & Hay, 1989). In particular, it is possible that rates of helping among the older children in the altruism condition were underestimated in the current study if such factors were in operation. One way future research might address this question is by manipulating the circumstances under which helping occurs, such as presence of parents or other adults in the room, or manipulating the value of the to-be-shared object in addition to whether it belongs to the child or not.

In sum, the findings of the current study reveal an important developmental transition at the end of the 2nd year of life when toddlers' helping behavior expands to include empathic as well as instrumental helping. The results point as well to the late emergence of altruistic helping, after other-oriented helping first becomes evident, inasmuch as even 2-year-olds find costly helping especially difficult. This suggests that changes in social understanding and prosocial motivation may be closely linked, with other-oriented concern developing in concert with growth in children's ability to represent and understand others' subjective internal states, and altruistic helping developing later, in concert with understanding of social and moral norms. It would be productive in future research to investigate these links more directly, possibly by including additional measures of self- and other-understanding and empathy, as well as by testing older children in situations that require various types of helping.

Do Black and Hispanic Children Benefit More From Preschool? Understanding Differences in Preschool Effects Across Racial Groups

Daphna Bassok
University of Virginia

Recent studies suggest that the effects of attending preschool vary by race. These findings are difficult to interpret because the likelihood of enrolling a child in preschool also differs across groups. This study used newly released, nationally representative data to examine whether the impact of preschool participation at age 4 varies across racial groups after accounting for selection differences (N = 7,400). Among a subsample of children living below a poverty threshold, no racial differences in preschool impact are detected. However, findings suggest that nonpoor Black children benefit substantially more from preschool than their nonpoor White or Hispanic peers. Implications of these findings are discussed toward understanding the potential of large-scale preschool interventions for narrowing racial achievement gaps.

The achievement gap between White children and Black and Hispanic children is a persistent and widely documented policy concern (Fryer & Levitt, 2004; Reardon & Robinson, 2008). Racial gaps in cognitive ability emerge years before children enter elementary school (Fryer & Levitt, 2006; Haskins & Rouse, 2005; Loeb & Bassok, 2008). A growing body of research provides strong evidence that preschool programs can have positive and long-lasting effects on a host of academic and social outcomes (Belfield, Nores, Barnett, & Schweinhart, 2006; Garces, Thomas, & Currie, 2000; Ludwig & Miller, 2007; Reynolds, Temple, Robertson, & Mann, 2001). Together, these two facts have led to growing consensus that preschool programs are a critical component of any policy agenda aimed at ensuring children—irrespective of their race or socioeconomic status (SES)—can succeed in school.

If preschool interventions are to meaningfully narrow achievement gaps, however, at least one of two conditions must hold. Either programs must be targeted specifically toward low-income or minority populations or the effects of program participation must be larger among these groups. As a growing number of states and communities move away from economically targeted preschool programs, expanding or even universalizing their preschool initiatives, it is particularly important to understand whether program impact varies systematically across groups of children (Barnett, Epstein, Friedman, Boyd, & Hustedt, 2008).

Many studies demonstrate that the effects of preschool are greatest for poor children (Garces et al., 2000; Gormley & Gayer, 2005; Magnuson, Ruhm, & Waldfogel, 2007). Several recent studies suggest that even after controlling for SES, the effects of attending preschool in the year before kindergarten entry are also larger among Black and Hispanic children relative to White children (Gormley & Phillips, 2005; Loeb, Bridges, Bassok, Fuller, & Rumberger, 2007). These findings suggest that preschool—even when widely available—might offer a promising strategy for reducing or eliminating racial achievement gaps.

To date, however, research has not examined *why* preschool effects might vary by race. The current study aims to fill this gap, focusing in particular on differential selection processes across groups as one possible explanation. In 2005, 43% of Hispanic children aged 3–5 attended preschool. White and Black children participated at far higher rates, 59% and 66%, respectively (Rooney et al., 2006).

This research was supported by a grant from the American Educational Research Association that receives funds for its "AERA Grants Program" from the National Science Foundation and the National Center for Education Statistics of the Institute of Education Sciences (U.S. Department of Education) under NSF Grant DRL-0634035. Additional support was provided by the Stanford Graduate Fellowship. Opinions reflect those of the author and do not necessarily reflect those of the granting agencies. These large differences in participation might partially explain the observed differences in effects.

The current study utilizes newly available data from the Early Childhood Longitudinal Study–Birth Cohort (ECLS–B) to examine whether the effects of preschool attendance at age 4 on cognitive outcomes differ by race. Throughout this study preschool refers to any classroom-based program targeted at 4-year-olds including nursery schools, preschool centers, and prekindergarten programs. The ECLS–B is the first study to track a large, nationally representative sample from 9 months to school entry. The availability of data on both family environment and children's cognitive ability at 9 months, which is before most children have started any formal nonrelative care, allows for a more thorough understanding of preschool impacts than has been previously possible using retrospective data.

Differential Preschool Outcomes

Children who attend preschool in the year before kindergarten entry tend to start school with higher cognitive skills than similar children who stay with their parents (Barnett, 1995; Currie, 2001). Experimental studies demonstrate that for very poor Black children attending a high-quality preschool can yield positive effects across a variety of domains well into adulthood (Campbell, Ramey, Pungello, Sparling, & Miller-Johnson, 2002; Schweinhart et al., 2005). Because of their highly targeted populations, however, these studies tell us little about the potential impact of preschool for nonpoor or non-Black children. In order to make comparisons across socioeconomic and racial groups, researchers have turned to nonexperimental data. Large-scale studies show that the effects of attending preschool at age 4 are largest among poor children (Garces et al., 2000; Gormley & Gayer, 2005; Magnuson et al., 2007).

Recent studies suggest that the relation between preschool and child outcomes also differs across racial groups, even after accounting for a host of socioeconomic measures. Using the kindergarten cohort of the ECLS, Loeb et al. (2007) show that the association between preschool participation and reading scores at kindergarten entry is almost 3 times larger among English-proficient Hispanic children than among White children. The effects for Black children are between those of White and Hispanic children.

Similarly, in their quasi-experimental study of universal prekindergarten in Oklahoma, Gormley and Phillips (2005) find that among Hispanic children, preschool participation leads to a 54% improvement on a cognitive assessment compared with no significant effects for White children and a 17% improvement among Black children. Finally, in their study of Head Start, the federally funded preschool program targeted toward low-income children, Currie and Thomas (1999) use within-family comparisons and show that Hispanic Head Start attendees experience particularly large boosts in test scores. They estimate that Head Start participation closes approximately one fourth of the Hispanic–White test score gap.

Explaining Differential "Effects"

The results from these studies suggest that preschool participation might be a powerful tool for reducing racial achievement gaps. However, the mechanism that explains the differences has not been investigated. There are at least five plausible explanations for differences in preschool effects across groups.

First, differences in preschool effects could be driven by differential selection patterns across racial groups. Recall that Hispanic children attend preschool programs at significantly lower rates than White children and that Black children attend at the highest rates. If the Hispanic children who attend preschool are a more "selective" group than their White or Black counterparts then an estimation strategy that fails to explicitly control for these differences would artificially inflate the effects of preschools for Hispanic children. Here "selective" might mean they would have performed better relative to their peers irrespective of care choice but could also mean that relative to other racial groups, Hispanic preschool attendees are more likely to be those who stand to gain the most from preschool.

Previous studies that have explored differences in preschool effects across groups have attempted to adjust for this type of nonrandom selection into preschool. However questions about selection and generalizability remain. For instance, although Loeb et al. (2007) are able to control for the many child and family characteristics available in the ECLS–K, in that study the data were collected *after* the child finished preschool as they were entering kindergarten. There are no measures of pretreatment cognitive outcomes, and no way to definitively check whether observed differences in preschool effects across racial groups are biased by racial differences in pretreatment characteristics. The quasi-experimental research design employed in the Oklahoma study relies on comparisons between children who are quite similar in age but due to their birthdays and to the state's enrollment cutoff for prekindergarten, enroll in the state program 1 year apart. Although the approach provides unbiased estimates of the effects of preschool for children who eventually enroll, it does not address differences between participants and nonparticipants. Because participation rates differ across racial groups, the authors caution readers against making across-group comparisons about program effects.

A second possibility for the observed racial differences in preschool effects is that race is serving as a proxy for other child characteristics, such as poverty or English language ability. The overrepresentation of Black and Hispanic children among groups who may benefit disproportionately from preschool might explain the observed differences in the impact of preschools. As discussed earlier, studies have repeatedly found that the effects of preschool are largest among poor children. Evidence of a differential preschool effect for English language learners is more mixed. Consistent with the hypothesis that preschools are particularly beneficial for children who are learning English, a study of Oklahoma's prekindergarten program shows that Hispanic children whose parents speak Spanish at home benefit far more from preschool than those whose parents primarily speak English (Gormley, 2008). However, other studies have not found stronger preschool effects for nonnative English speakers (Crosnoe, 2007; Currie & Thomas, 1999; Magnuson, Lahaie, & Waldfogel, 2006).

A third possibility is that group differences in preschool experiences might be part of the explanation for differences in effects. If the nature of the preschool intervention differs across racial groups, analyses that fail to account for these key details may lead to ''apples to oranges'' comparisons. For instance, exposure to preschool, in terms of both hours per week and age at entry, varies by race with Black children starting preschool younger and attending for more hours than their White or Hispanic peers (Gormley & Phillips, 2005; Rumberger & Tran, 2006).

Preschool quality also differs across groups. The Cost, Quality and Outcomes Study shows that White children attend preschools that are almost one third of a standard deviation higher on an aggregate quality rating relative to those attended by Black children (Burchinal & Cryer, 2003). Similarly, although 41% of White preschoolers in California have a teacher with an associate's degree or higher in early childhood education, the figure is 34% for Latinos and 13% for Blacks (Karoly, Ghosh-Dastidar, Zellman, Perlman, & Fernyhough, 2008). It is important to note, however, that if these quality differences are driving differences in preschool effects across groups, we would expect Black and Hispanic children to experience *smaller* benefits from care relative to White children. In fact, we observe the opposite.

A final explanation is that the experience of *not* attending preschools may differ across groups. Many studies of preschool compare children who participate to those who use an alternate arrangement—oftentimes parental or relative care (Loeb, Fuller, Kagan, & Carrol, 2004; Magnuson et al., 2007; NICHD Early Child Care Research Network, 2006). The experience of being in this control group may vary across racial groups if, for example, exposure to enrichment activities or linguistic stimulation differs. If this is the case, then even at the same levels of care quality and exposure, children from certain racial groups may benefit more.

Racial Differences in Selection Into Preschool?

The current study focuses on the first posited explanation that racial differences in preschool effects are explained by differences in selection across groups. Several studies have modeled selection into preschool based on family characteristics (Huston, Chang, & Gennetian, 2002; Liang, Fuller, & Singer, 2000; NICHD Early Child Care Research Network, 1997). Family income is consistently a key predictor of preschool participation. Children whose parents are in the top income quartile are 23 percentage points more likely to attend early education programs than those in the bottom quartile (Bainbridge, Meyers, Tanaka, & Waldfogel, 2005). At the same time, government preschools have traditionally been targeted toward children in poverty, such that very poor children participate at higher rates than near-poor families (Meyers, Rosenbaum, Ruhm, & Waldfogel, 2004).

Many of the family characteristics that are predictive of care choice (i.e., income, maternal education and employment and family structure) differ across racial groups. For example, the ECLS–B data show that Hispanic children are much less likely than non-Hispanic White children to have working mothers or to live with a single parent, both traits associated with preschool participation. Group mean differences such as these may explain, at least in part, the differential rates of participation. Care choices may vary by race even when comparing families who are observably identical in resources.

One explanation may be omitted variables. For instance, cultural norms and beliefs about family and childrearing influence care decisions but are rarely observed by researchers (Liang et al., 2000). If these types of beliefs vary across groups, they may play a role in explaining selection differences (Fuller, Eggers-Pierola, Holloway, & Liang, 1996). In addition, child-care supply may differ by groups and non-English speakers may have trouble accessing child-care information (Liang et al., 2000).

The Current Study

In this study I use ordinary least squares (OLS) and propensity score matching to estimate the effects of preschool participation at age 4 on cognitive outcomes. I examine whether the racial differences in preschool effects reported in several recent studies are replicated in the ECLS–B. This study contributes to the existing literature in two important ways. First, because of the unique strengths of the ECLS–B data, the study allows for a more careful estimation of preschool effects than has been possible with previously used data sets. The ECLS–B data are large and nationally representative, collected before and during child-care use, and include unusually rich measures of child and family characteristics. At every wave parents are asked detailed questions about their child's current and previous child-care use. The ECLS–B therefore provides a much richer picture of children's care trajectories from birth onward than other data sets commonly used to study child care. Further, because the ECLS–B relies on prospective rather than retrospective reports of care use, there is less risk of recall error (Bound, Brown, & Mathiowetz, 2000).

The ECLS–B also provides detailed ''pretreatment'' data on children and their families. Although certain characteristics such as race or gender will not change due to care participation, others, such as children's cognitive abilities or parents' reading habits, might. Many studies estimate preschool effects using data from the years *during* or *after* the child enters care. This makes it difficult to sort out causality. For instance, are parents who read to their children often more likely to send their children to preschools, or does sending children to preschools raise parents' awareness of the importance of reading? Having data collected *before* children enter care eliminates a major hurdle in estimating causal relations.

The second way this study adds to the literature is by distinguishing racial differences in preschool effects from socioeconomic differences. This is an important point when trying to accurately gauge the impact of current preschool expansion initiatives on racial achievement gaps. In a recent study, Magnuson and Waldfogel (2005) provide back-of-the-envelope estimates of how various preschool expansion models might affect racial achievement gaps. Their calculations suggest that programs that specifically boost Hispanic and Black enrollment in preschool will be the most powerful for narrowing gaps. However, their analysis does not take into account that the effects of preschool differ, both across race and across socioeconomic groups. They might therefore underestimate the possible gains from a universal preschool system. The current study provides estimates of preschool effects across racial subgroups in order to enhance our ability to predict the impact of preschool expansions on racial achievement gaps.

Method

Participants

This study relies on data from the ECLS–B, which is the first nationally representative study to track children from birth through school entry. Data are currently available from the first three waves when the children are approximately aged 9 months, 2 years, and 4 years. The base sample includes approximately 10,700 infants born in 2001 who were selected primarily from the National Center for Health Statistics vital statistics system. Note that in compliance with National Center for Education Statistics rounding rules, all sample sizes presented in this study are rounded to the nearest 50. A cluster list-frame design was used, and primary sampling units were defined by contiguous counties. Children who died or were adopted before 9 months were excluded, as were children born to mothers younger than age 15.

A key goal of the current study is to investigate the impact of preschool at age 4 controlling for child and family characteristics at earlier waves. To accomplish this, the analytic sample is limited to children who were still in the sample at the 48-month wave. The analytic sample includes all children for whom child care and family data were collected at each wave and for whom cognitive assessments were conducted at every wave. Due to attrition, this restricted sample includes approximately 7,500 children. Children who remained in the sample and were assessed at the 48-month wave differed from those who attrited or were not tested on a host of observable characteristics. The ECLS–B provides a series of sampling weights to account for this nonresponse and to allow for population-level estimates. In all analyses presented in this study, I reweight the sample using the W3C0 weight that is designed specifically for studies that consider cognitive outcomes during the 48-month wave based on child and family measures from the previous two waves. I eliminate approximately 150 additional observations (2%) due to missing data on key covariates. Specification checks in which I impute this missing data yield almost identical results. The final analytic sample includes approximately 7,400 children.

Measures

At every wave, trained interviewers conducted home visits that included detailed parent interviews and direct child assessments. Data were collected from parents using computer-assisted personal interviewing as well as self-administered questionnaires. In almost all cases, the focal child's mother or female guardian completed the interview (100% at the 9-month wave and 95% at the 48-month wave). The interview protocol was programmed in both English and Spanish, and bilingual interviewers as well as interpreters were available to assist parents (Snow et al., 2007).

Child-care arrangements. Parent-reported child-care information was used to identify each child's primary arrangement. I constructed five mutually exclusive groups to delineate primary care type at 48 months: preschool, Head Start, nonrelative care, nonparental relative care, and parental care. Preschool is defined as any classroom arrangement including day care programs, private or public centers and state prekindergartens, but excluding Head Start. Head Start is a federally funded intervention targeted toward very low-income children. It is unique from other preschool programs both in its funding and its commitment to comprehensive services including health, nutrition, and social services. Nonrelative care encompasses arrangements with home child-care providers, nannies, babysitters, or neighbors.

I defined primary care type based on total time spent in a particular care *type*. For instance, if a child attended two separate preschools, I classified them based on the total time spent in both settings. Further, if a child spent *any* time in a nonrelative, preschool or Head Start setting, they were categorized as using that care type even if they spent more hours in parental or relative care. For the 9- and 24-month waves, there are only four possible arrangements; Head Start primarily serves 3- and 4-year-olds, and questions about Head Start were only introduced in the third wave.

Cognitive outcomes. During the third wave of data collection, cognitive assessments were conducted as close as possible to the fall of the "preschool" year. Although the bulk of children were assessed between August and December 2005, some children were assessed as late as June 2006 (Snow et al., 2007). The cognitive assessments during this "preschool" wave were designed specifically for the ECLS–B study and include items from several reliable early assessments including the PreLAS 2000, the Peabody Picture Vocabulary Test, the Preschool Comprehensive Test of Phonological and Print Processing, and the Test of Early Mathematics Ability (Duncan & DeAvila, 1998; Dunn & Dunn, 1997; Ginsburg & Baroody, 2003; Lonigan, Wagner, Torgeson, & Rashotte, 2002). Items were also taken from the Family and Child Experiences Study, the Head Start Impact Study, and the ECLS–K (Zill & Resnick, 1997). The literacy assessment includes measures of phonological awareness, letter sound knowledge, letter recognition, print conventions, and word recognition. Throughout the analysis I use standardized scores with a mean of 50 and a standard deviation of 10. These *T* scores provide norm-referenced measures of student achievement.

Cognitive assessments for the first two waves were conducted as close as possible to age 9 and 24 months, respectively. In these two earlier waves, cognitive ability was assessed using the Bayley Short Form–Research Edition (BSF–R), which was designed specifically for the ECLS–B and is made up of selected items from the Bayley Scale of Infant Development (Second Edition), an instrument commonly used by psychologists to assess the development of infants and toddlers (Bayley, 1993; Psychological Corporation, 2001). At 9 months, the BSF–R measures infants' ability to explore objects, explore objects purposefully, babble, do early problem solving and communicate with words. At 24 months, the BSF–R includes measures of memory, means-end behavior, exploratory competence, object permanence, expressive communication, and receptive communication.

A striking feature of the test scores is the emergence of cognitive gaps across racial groups between the first two waves (see Fryer and Levitt, 2006, for a discussion). The top panel of Table A1 in the Appendix shows that, at the 9-month wave, the raw achievement gap between Whites and other groups ranges from a statistically insignificant .06 of a standard deviation for Hispanic children from homes in which English is the primary language and .15 of a standard deviation for Black children. By the 24-month wave, this gap has grown to .36 for Hispanic children from homes in which English is the primary language, .53 for Black children, and .78 for Hispanic children from homes in which Spanish is the primary language. Direct comparisons of the achievement gaps at 24 and 48 months are not possible because different metrics are used to assess qualitatively different skills. Nonetheless, the cognitive gaps at the ''preschool wave'' are substantial.

Race and ethnicity. Children's race is defined based on parent reports during the 9-month wave. I report results for children whose parents identified them to be White, Black, or Hispanic. Due to small sample size, preschool impacts for other subgroups (Asians, Pacific Islanders, American Indians, and children classified as ''other'' or ''multiple'') are not reported. The Hispanic subgroup is further divided based on whether English is the primary language spoken in the home. This measure is meant to proxy for both English proficiency and acculturation. Cabrera, Shannon, West, and Brooks-Gunn (2006) argue that language ability, which is correlated with years in the United States, provides a robust measure of acculturation. Other controls for English proficiency and acculturation include: whether English is *ever* spoken in the home, if the mother indicated she speaks English ''not very well'' or ''not well at all,'' and whether the mother was born in the United States.

Socioeconomic status. Several measures are used to account for SES. The first is a standardized continuous, composite variable constructed based on parent-reported information from the 9-month wave ($M = 0$, $SD = 1$). Components of this SES index include household income, parents' employment status and parents' education level. The ECLS–B also provides a set of composite variables that use family income and size to determine whether a family is above or below various federal poverty thresholds. In this study analyses are disaggregated based on whether a family is below 130% of the poverty line. Just over one third of the sample is in this group, although there are substantial differences by race. Approximately 21% of White children in the sample are below 130% of the poverty line. The figure is 60% for the Black children, and 49% for Hispanic children. Despite the fact that most Black children in the sample are below the threshold, there are still approximately 450 Black children above this poverty threshold, providing a sufficient sample size for this subgroup analysis.

Additional covariates. A key advantage of the ECLS–B is the availability of extremely detailed information about family resources and environment. I make use of a large set of the covariates to better account for nonrandom selection into care. Descriptive statistics for these covariates, measured at the 9-month wave unless otherwise noted and disaggregated by race, are presented in the lower panel of Table A1 in the Appendix. First, I account for key child characteristics as reported on birth certificates. These include age (calculated from date of birth), gender, birth weight, multiple status, and birth order.

Next, I control for maternal employment and educational attainment as well as family structure because these factors are known to be strong predictors of care choice and also differ by race. Maternal employment is included in the model using three indicator variables (mother works full-time, mother works part-time, mother is unemployed). Mother's educational attainment is entered into the model as three indicator variables as well (mother did not graduate from high school, mother went to a vocational school or completed some college, and mother has a bachelor's degree or an advanced degree). To account for family structure, I control for whether the child is being raised by a single parent, the age of the mother when she had her first child, and the number of children and adults living in the home.

An additional set of covariates is included to more thoroughly account for differences in family resources and to capture use of targeted public programs. These include: whether the family experienced food insufficiency (medium and high food insufficiency are defined based on the frequency with which food is lacking in the home); whether the family received benefits from the Nutrition Program for Women, Infants, and Children (WIC) in the past year; whether the family received Food Stamps or welfare since the child's birth; whether the family owns a car; and whether they live in government-subsidized housing.

The ECLS–B also includes measures of parenting practices, home-learning environment, maternal stress levels, and social support. These variables are included because they capture traits that are likely to be correlated with child development and potentially are also correlated with care choice. Measures of parenting and home environment include: whether the child was breast fed, frequency of joint book reading in the home, and mother's knowledge of basic child development concepts (sum of 11 items about typical child development). Measures of community and social support include whether the mother indicated she had anyone to turn to in stressful situations (i.e., emergency, needing parenting advice, needing to borrow money) and whether she was involved in a church on a weekly basis. Differences in these measures of social support may be important for predicting differences in preschool care utilization across groups.

Finally, the models control for region of the United States (Northeast, Midwest, South) and community type (rural, suburban). These are included to account for regional differences in resources, services for children and preschool availability.

Data Analysis

I estimate OLS regressions predicting each child's literacy score at the preschool wave (roughly 48 months) as a function of their current primary care type, which is measured with a series of indicator variables. Children in parental care serve as the omitted (or base) category. Models are adjusted for each child's age at the time of the 48-month assessment, as well as a vector of controls (discussed earlier) that adjust for child and family characteristics as reported at roughly 9 months. I then interact each of the nonparental care types (preschool, Head Start, nonrelative, and relative) with each of the racial indicators to measure whether the impact of preschool varies significantly across groups. Identical models predicting mathematics ability are also explored. They yield substantively similar results and to save space are omitted.

The OLS models rely on the rich set of controls available in ECLS–B to adjust for key differences in child and family characteristics across care type. These models provide plausible estimates of preschool effects only if *all* relevant covariates are included; omitting a variable that is correlated with the outcome and predictive of preschool use will bias the results. There is no way to explicitly test whether all relevant variables are included, however, the rich set of controls available make the assumption more credible than has been possible with previously used data.

As a specification check I also replicate each analysis using a multinomial propensity score matching approach (Lechner, 2002; Robins, Hernán, & Brumback, 2000). Although the rich set of controls available in the ECLS–B goes a long way toward reducing selection bias concerns, a potential problem with the OLS models is extrapolation beyond the region of ''common support.'' To make compelling causal claims about the effects of a particular treatment, we would ideally like to compare observably similar individuals who both did and did not participate in the treatment. However, if some of the people who experienced a particular treatment are completely different from any of the people who did not receive the treatment, we cannot accurately measure the effect the treatment had for this group. Using OLS, inferences are made over the entire range of the data, even in areas, where there is no common support. Propensity score matching provides one useful solution to this problem by explicitly identifying the region of common support and eliminating observations for which no appropriate controls exist.

Matching strategies have become increasingly common for estimating treatment effects. Each individual who receives a particular ''treatment'' (i.e., preschool care) is matched to one or more individuals who are similar on observable pretreatment characteristics but did not experience the treatment. Assuming that individuals are matched on *all* factors that influence both selection decisions and child outcomes, the matched pairs simulate an experimental design. Researchers typically identify ''similar'' individuals based on their propensity score or their probability of receiving the treatment. I estimate each individual's likelihood of being in each of the five care arrangements using a multinomial logit model that includes the covariates described earlier and several higher order terms. Following cutoff suggestions presented in Caliendo and Kopeinig (2008), I then limit the sample to children for whom causal inferences can more reliably be made. I reweight the data using inverse probability of treatment weighting (IPTW; Robins et al., 2000). Each individual's observation is reweighted by the inverse of their probability of being in their actual treatment group. This reweighting process reduces selection bias by giving higher weights to children who could plausibly be in treatments other than the one in which they are observed. Without IPTW reweighting, almost all of the covariates in the model are significantly related to care choice. In other words, children in each care type during the 48-month wave differ systematically from each other on most characteristics observed at 9 months. Once reweighted, race is no longer systematically related to treatment and the bulk of covariates do not differ in significant ways by care type. A table showing these differences before and after reweighting is available from the author upon request.

Distinguishing racial differences from income differences. In the final portion of the analysis, I examine the extent to which observed differences in preschool effects across racial groups are driven by SES differences. I explore this issue by reestimating the regression model with Race × Preschool interaction terms for the subsamples below and above a poverty threshold. I also run regressions on the full sample, but add an SES × Care interaction term. The purpose of both sets of models is to assess whether allowing preschool effects to vary with SES eliminates the observed racial differences.

Results

Results are presented in three sections. First, differences in preschool use across groups are highlighted. The second section presents OLS and propensity score matching estimates of the effect of preschool participation on literacy outcomes at roughly 48 months. Both aggregate impact and differences across racial groups are considered. The final section describes results from models that allow the impact of care to interact with SES.

Differences in Care Participation

Table 1 shows child-care participation rates across waves as well as racial groups. The first column presents trends for the full sample. When the children are approximately 9 months old, about half are cared for solely by their parents and another quarter have a regular care arrangement with relatives. At this early age, less than 10% of children attend a preschool. When the children are approximately 24 months, half are still in parental care but there is a shift from relative care to preschool, with approximately 17% of children in each of these groups. Many preschool programs are targeted toward 4-year-olds, so it is not surprising that the most meaningful changes in primary care type occur between the 24- and 48-month Waves. At the 48-month wave, the percentage of children in parental and relative care drops to 18% and 7%, respectively, whereas more than two thirds are enrolled in either a preschool or Head Start program.

The trends for the full sample mask substantial differences across race. In the first two waves, Black children attend preschool at a much higher rate than other children. At the 24-month wave, for example, 26% of Black children are enrolled in preschool compared with 17% and 12% of White and Hispanic children, respectively. At the 48-month wave, the distribution of children between preschool and Head Start also varies substantially by race. Sixty percent of White children are enrolled in preschool and only 8% are enrolled in Head Start. In contrast, 32% of Black children and 21% of

Table 1
Primary Care Participation by Race and Ethnicity (9, 24, and 48 Months)

Primary care	Full sample	White	Black	Hisp	Hispanic English	Hispanic Spanish

N[a]	7,400	3,400	1,150	1,300	750	550

Note. Each column represents a subgroup, and the table is populated with the proportion of children in that subgroup who use a particular form of care at each wave.
[a] In compliance with National Center for Education Statistics rounding rules, all sample sizes are rounded to the nearest 50.

Hispanic children use Head Start as their primary care choice.

The table also highlights differences in care utilization between Hispanic subgroups. Relative to Hispanic children whose families primarily speak English in the home, Hispanic children whose parents primarily speak Spanish are more likely to be in parental care. They are also more likely to enroll in Head Start than in a preschool. The large differences in preschool utilization across racial and ethnic groups highlight the need to account for selection differences in estimating the impact of preschool participation.

Aggregate Effects of Preschool Participation

Table 2 presents OLS and propensity score matching estimates of the associations between care type and literacy outcomes, both measured during the 48-month wave. Column 1 shows estimates of the ''raw'' associations between care type and child outcomes, adjusted only for the child's age at assessment and age squared. Parental care is the omitted category. This first model highlights substantial differences in cognitive outcomes by primary care choice. Children who attend preschools score more than 4.5 points higher on the literacy assessment. Recall that the cognitive assessments are normed with a standard deviation of 10, so these coefficients amount to just under half a standard deviation. Children in nonrelative care also outperform those solely in parental care by about 2.3 points. In contrast, those in relative care perform about 1.7 points worse. Notably, in these unadjusted models Head Start attendees perform about as well as children who stay at home with their parents. Given the high levels of poverty that characterize Head Start participants, it is surprising that the unadjusted Head Start coefficients are not negative.

These ''raw'' estimates are not appropriate measures of the causal impact of care choices as they do not account for *any* child or family characteristics. In Column 2, I control for child gender and birth weight, SES, participation in WIC (a needs-based nutrition program), and mother's age at first childbirth. These covariates were selected based on Fryer and Levitt (2004), which shows that this short list of characteristics explains away the achievement gap between Whites and Blacks at kindergarten entry. Accounting for these variables reduces the association between preschool and literacy outcomes substantially, though the coefficient for preschool is still large and highly statistically significant. Not surprisingly, the Head Start coefficient increases once I account for these basic controls. In fact, the Head Start coefficient is not significantly different from the coefficients for preschool.

Column 3 shows results from models that also control for race. After accounting for the key demographic variables, race does not substantially alter

the results or add much explanatory power. In fact, the results remain stable in column 4 when I add the full set of child and family characteristics from the 9-month wave, including the child's 9-month mental and motor assessments.

Four alternative specifications were also considered, although results are not shown. First, a model that controls for children's cognitive outcomes at the 24-month wave suggests slightly higher preschool and Head Start coefficients. However, due to the substantial number of children who already attend preschool by the second wave, I worry that including cognitive measure from the 24-month wave adds endogeneity to the model. A second, more flexible model interacts race with key child and family characteristics (i.e., child's gender, maternal education, etc.). Although some of these interaction terms are significant predictors of cognitive outcomes, including them has no impact on the child-care coefficients. Finally, I consider models with state and then county fixed effects to account for unobservable, within-region characteristics that may be related to care choices as well as cognitive outcomes. Again, adding these fixed effects does not meaningfully impact the preschool or Head Start coefficients.

For simplicity and ease of interpretation, I prefer the model shown in column 4 and move forward with it for the remainder of the study. The results from this specification suggest that preschool participation is associated with literacy outcomes that are .13 of a standard deviation higher than those observed for children in parental care. The association between Head Start and literacy outcomes is quite comparable (.14 of a standard deviation). Children in nonrelative or relative care perform about as well as their peers in parental care.

Column 5 shows analogous results from the propensity score models. The first thing to note is that once the analysis is limited to the region of common support, the sample size drops from approximately 7,400 to 6,600. Eliminating observations outside the region of common support involves an inherent trade-off. The new sample includes children who are observably more similar, and therefore more appropriate for causal analysis. On the other hand, by eliminating observations I am left with a smaller sample, less precision, and potentially less generalizability. In the current analysis, the 10% of the analytic sample that lies outside the region of common support is very different from those within. They are more likely to be White or Asian and their SES is much higher. Although 25% of mothers in the region of common support have acquired a bachelor's degree or more, the figure is 70% for the omitted group. The omitted group is also about 15 percentage points more likely to be enrolled preschool (67% vs. 52%).

The results from the propensity score estimates are very similar to the original OLS estimates. The estimated effect of preschool is stable and the estimated impact of Head Start rises somewhat (from 1.4 to 1.8). This modest change is in the expected direction given that children with no appropriate matches are eliminated. Rerunning the OLS model on the same subset of children yields comparable results (see column 6). Given the extensive covariates available in the ECLS–B, it is not surprising that the two approaches provide similar estimates. Both models show that preschool participation is associated with just over one tenth of a standard deviation higher literacy outcome. The point estimates for Head Start, though not statistically different from those reported for preschool, are slightly higher.

Differences in Preschool Effects by Race

A key goal of this study is to examine whether the preschool effects shown earlier differ systematically across racial groups. To get at this, I run a model predicting literacy outcomes based on the preferred specification (Model 4 of Table 2) and a set of Race × Care interaction terms. Results from this model are presented in the top panel of Table 3. The first column shows main effects, which can be interpreted as the association between care choices and test scores for the White subgroup. The main effects for preschool and Head Start are small in magnitude and statistically insignificant. In contrast, the interaction between Black and preschool is quite large and statistically significant. Black children who attend preschool score 3.4 points higher (or an effect size of 0.34) than their peers primarily in parental care. This is the sum of the main preschool effect (0.479) and the interaction term between preschool and Black (2.905). Among Hispanics, the preschool interaction terms are statistically indistinguishable from those of Whites, although for children from primarily Spanish-speaking families the magnitude of the point estimate is large. Further, among both Hispanic subgroups, the estimated impact of participating in Head Start is substantial (effect sizes = 0.29–0.32) and higher than the insignificant effect observed among White children.

The p value on the joint F test that the Race × Preschool interactions jointly equal zero is

Relative	−1.342 (1.125)	0.264 (2.833)	1.532 (2.174)	−1.119 (2.228)	.8800
p value[b]			.7611	.0463	

Note. Each panel represents a single regression of children's test scores on their care type and a set of Care × Race interactions. Models also include the full set of control covariates. Interactions between care choices and the "other" and "multiple" race groups are also included such that the main effect can be interpreted as the effect for White children. Sample size (rounded to nearest 50): Panel 1–7,400; Panel 2–2,500; Panel 3–4,900. Standard errors are in parentheses.

[a]For each care type, are the Care × Race interactions jointly significant? [b]For each race, are the Care x Race interactions jointly significant?

†$p < .10$. *$p < .05$. **$p < .01$.

easily rejected ($p = .004$). The model provides support for the claim that the effects of preschool vary systematically by race. Results from identical models that use the propensity matching approach (not shown) are similar; however, the interaction terms between Head Start and each of the racial subgroups are significant at the .1 level, and F tests imply that both the Race × Preschool and Race × Head Start interactions are jointly significant.

Taken together the results suggest differences in the impacts of early childhood interventions across groups. Black children appear to benefit more from attending preschool relative to White children, and there is some indication that the impact of Head Start may also differ across groups.

Explaining the Racial Differences: Race as a Proxy for Resources

One candidate explanation for the differences in preschool effects across groups is that race is serving as a proxy for economic resources. Previous research suggests that low-income children experience greater returns from preschool interventions relative to children whose families have more resources. This relation is also observed in the ECLS–B. Table 4 shows that children whose families have the lowest income to poverty ratios experience large and significant preschool effects. In

Table 4

Ordinary Least Squares Estimates of the Effects of Child-Care Settings on Literacy Outcomes by Income-to-Needs Ratio (Lowest Quartile, Middle Half, and Upper Quartile)

	Low	Middle	High
Preschool	3.369*** (0.685)	0.766 (0.482)	−0.786 (0.994)
Head Start	2.181** (0.678)	1.421* (0.629)	N/A
Nonrelative	0.383 (1.033)	−1.132 (0.716)	−1.507 (1.266)
Relative	0.727 (0.876)	−1.580* (0.720)	N/A
R^2	.244	.246	.246
N	1,800	3,900	1,700

Note. The income-to-needs ratio is calculated as the ratio of a families' (approximate) income to the poverty level for a family of their size. The "low" category includes the bottom quartile of families whose income-to-needs ratio falls under 1.05 (just slightly over the poverty line. The "high" category includes the top quartile of families (income-to-needs > 4.09). Poverty thresholds were taken from the ECLS–B Preschool Year User's Manual. Estimates for Head Start and relative care are omitted from the final column due to small size. They each make up less than 3% of the observations in the high income-to-needs category. Standard errors are in parentheses. In compliance with National Center for Education Statistics rounding rules, all sample sizes are rounded to the nearest 50.

*$p < .05$. **$p < .01$. ***$p < .001$.

contrast, among the middle half of the sample and the top quartile there is no association between preschool and cognitive outcomes. Because Black and Hispanic children are overrepresented in the lowest group, it may be the case that poverty status explains what appears to be differential effects by race.

The two lower panels of Table 3 present results from OLS models with Race × Care interactions estimated separately for subsamples below and above 130% of the poverty line. If differences in the impact of preschool across racial groups are driven by differences in their poverty status, Race × Care interactions will be weak predictors of cognitive outcomes in these restricted subsamples. This is, indeed, what the results from the poverty sample show. The main preschool effect, which corresponds to the impact of preschool for poor White children, is large and significant (.26 of a standard deviation) and the Race × Care interactions are negligible. This model suggests that on average all low-income children—irrespective of race—respond positively and fairly similarly to preschool participation. This is consistent with the "race as a proxy for resources" explanation.

Among families above 130% of the poverty line, the main effects are small and insignificant. For White children in this subsample, children who attend preschool perform as well as children who are primarily in parental care. If all children living above the poverty threshold responded similarly to preschool, the Race × Preschool interactions would again be insignificant. This is not the case. The results show that the impact of preschool for both Black children and Hispanic children whose families primarily speak Spanish is large and significantly greater than the impact for White children. Although I cannot reject the null hypothesis that the set of Race × Preschool interaction terms are all equal to zero, the magnitude of the coefficients suggests that among the nonpoor sample, preschool impacts may differ with race.

Table 5 shows results from similar OLS models with added interaction terms between SES and each care type. Including these interaction terms allows me to retain the full sample and is more flexible than using a relatively arbitrary poverty cutoff. The results indicate that the interaction between preschool and SES is negative and significant. This again suggests that the benefits of preschool over parental care diminish as family resources rise. Accounting for this SES × Preschool interaction, however, does not eliminate the large and significant coefficient on the Black × Preschool interaction. Further, even when accounting for the interaction between SES and preschool attendance, I can still reject the null hypothesis that the Race × Preschool interactions are jointly equal to zero ($p = .004$).

As a final check, I also run OLS regressions separately by race, and include the SES × Care interaction terms (see Table 6). These models are somewhat more flexible than the pooled model with Care × Race interactions because they allow each of the covariates in the model to operate differently across racial groups. The interaction term is negative in the full sample as well as for Whites and Hispanics. In contrast, among Black children, the SES × Care interaction is actually positive, and marginally significant ($p = .110$). Among Black children the positive effects of preschools do not appear to be inversely related with poverty.

Table 5

Ordinary Least Squares Models Estimating the Relation Between Care Choices and Literacy Outcomes at the 48-Month Wave, Including Race × Treatment and SES × Treatment Interactions

Literacy	Main effects (White)	Black	Hispanic-English	Hispanic-Spanish	SES	p values[a]
Preschool	0.554 (0.478)	1.987† (1.151)	0.464 (1.070)	0.644 (1.217)	−1.466** (0.503)	.0039
Head Start	0.445 (0.820)	0.436 (1.281)	1.993 (1.429)	1.906 (1.359)	−1.120 (0.740)	.4861
Nonrelative	−1.195† (0.694)	0.398 (1.755)	2.293 (1.754)	0.013 (1.849)	−1.112 (0.688)	.7877

These analyses provide mixed evidence for the hypothesis that racial differences in preschool effects are capturing differences in SES. The models show that, on average, all poor children, irrespective of race, benefit from preschool participation relative to parental care. At the same time, after accounting for the interaction between family resources and preschool effects, Black children still seem to experience systematically higher returns to preschool participation. Further, their larger gains from preschool seem to be driven largely by the nonpoor sample.

Discussion

This study uses a large, nationally representative data set to investigate whether the impacts of attending preschool at age 4 vary across racial groups. States and communities are increasingly considering or implementing universal rather than targeted preschool interventions. In this context, estimating the differential effects of preschool is essential for understanding whether early interventions can realistically narrow racial achievement gaps.

Using OLS and propensity score matching, I find evidence that preschool effects vary both across racial groups and between Hispanic subgroups even after controlling for SES and an extensive list of child and family characteristics. For White children, the association between preschool participation and literacy scores is small and insignificant. In contrast, effect sizes are substantial and significant among Black and Hispanic children. For Black children, the estimated preschool effect size is 0.34, which is about 3 times larger than the preschool effects reported at kindergarten entry using the ECLS–K (Loeb et al., 2007). Both Hispanic subgroups appear to benefit from preschool participation, although the estimated effect sizes are larger for Hispanic children from primarily Spanish-speaking homes (0.22) than for those whose families primarily speak English (0.14). Further, there is evidence that, among Hispanic children, the effects of Head Start are also large, a finding that is consistent with the ECLS–K results.

Although these first set of findings stem from models that statistically adjust for a rich set of covariates, the models do not explicitly account for the possibility that the relation between preschool participation and child outcomes might vary with family resources. To get at this issue I rerun the analyses for poor and nonpoor subgroups and, more flexibly with interactions between each care choice and SES. The purpose of these analyses is to assess whether the differential effects of preschool across groups diminish once I allow the impact of preschool programs to vary with SES. Indeed, I find that among very low-income children, defined as those whose family income places them under 130% of the poverty line, racial differences in preschool effects are far less pronounced, and statistically negligible. On average, poor children (irrespective of race) perform about a quarter of a standard deviation higher on a literacy assessment than those children who are primarily in parental care.

Among the nonpoor sample, however, the returns to attending preschool (relative to staying home with a parent) are much larger for Black children and Hispanic children whose families primarily speak Spanish, than for their peers. Consistent with findings from previous studies, the results also indicate that among White and Hispanic children the effects of preschool are inversely related to SES, such that the benefits of preschool are largest among the poorest children. In contrast, among Black children the interaction between SES and preschool participation is actually positive, and marginally statistically significant ($p = .110$). These results are surprising and warrant further examination.

As part of the growing debate on universal preschool, researchers and policymakers are interested in whether preschool yields meaningful positive impacts for middle-income families (Barnett, Brown, & Shore, 2004). Several studies have highlighted positive short-term benefits from preschool attendance for nonpoor children (Gormley & Phillips, 2005; Loeb et al., 2007). The current study, which finds positive preschool effects for nonpoor Black children, provides some support for this finding. However, to the best of my knowledge, it is the first study to suggest that the benefits of preschool among nonpoor children may be more pronounced for some racial and ethnic groups.

Why might nonpoor Black children benefit more from preschool participation than their peers? In this study I posited several possible explanations for differences in preschool effects across race, and I revisit them now, in light of the current findings. One possibility is that nonpoor Black children have greater exposure to preschool than their White or Hispanic peers and that this more intense preschool experience might explain the positive gains. Data from the ECLS–B, as well as other studies, show that, on average, Black children start preschool at an earlier age, and attend for more hours per week (Magnuson & Waldfogel, 2005; Snyder & Hoffman, 2002). Though previous studies have not reported whether these patterns persist among nonpoor families, if they do then the differences in preschool effects might capture the cumulative benefits of more time spent in preschool.

Another possibility is that the nonpoor Black children have systematically different preschool experiences with respect to quality, content, or focus. A few studies find that on average Black children attend preschool programs that are of lower quality than those used by White children. However, these quality differences would suggest that—if anything—gains from preschool would be smaller for Black children than for White children. The quality explanation is therefore inconsistent with the findings from this study. Still, the few studies that examine differences in preschool quality across racial groups do not disaggregate results by family resources. It might be that among nonpoor families quality differences operate in the opposite direction. Perhaps nonpoor Black children are more likely than their peers to attend preschool programs that focus on the types of preliteracy skills that are assessed in the ECLS–B.

Finally, it might be that the observed differences in preschool effects across groups stem from differences in the activities and learning environments that children in the comparison group (those in parental care) experience. More research is necessary to better understand the home-learning environments of 4-year-old children who are primarily in parental care, and to see how experiences may vary across groups.

Although an empirical exploration of the various mechanisms that explain differences in preschool impacts across groups is beyond the scope of this current study, the ECLS–B does provide a unique opportunity to test some of the hypotheses posited. At each round of data collection, the ECLS–B asks parents about their child-care arrangements, and includes items that address age at entry and hours of participation. During the 24- and 48-month waves, the focal child's preschool teacher and preschool director were surveyed. These surveys provide extensive data on the structural characteristics of the child's preschool program as well as the curriculum and the teacher's beliefs. Finally, the ECLS–B asks parents many questions about the frequency with which various learning activities occur in the home (i.e., joint book reading, trips to the library, computer usage). In future analyses, these data can be used to better understand whether intensity of preschool exposure, preschool quality, and home-learning environment partially explain differences in preschool effects across groups.

Limitations and Remaining Questions

Although the current study provides important new insights about the differential impact of preschool participation across groups, the study has several limitations worth noting. First, the study does not account for variation in the amount of preschool children have experienced at the time of their 48-month wave assessment. Variation in exposure to preschool occurs for two reasons. First, some variation occurs because the data collection for the third wave of the ECLS–B was collected over the entire preschool year. Although most children were assessed in the fall, a substantial portion was assessed later in the year. Children who were assessed later are likely to have experienced greater amounts of preschool. Preschool exposure also varies across children due to true differences in the age at which children start preschool and the hours they participate each week. For example, among children who use preschool as their primary form of child care, the average age at first preschool experience is 32 months with a standard deviation of 17 months. Children attend preschool for an average of 23 hr a week, with a standard deviation of 14 hr. The current study presents average preschool effects without accounting for the possibility that preschool impact varies by differences in exposure.

The ECLS–B provides better data on children's child-care histories than any other nationally representative dataset, including detailed information about multiple arrangements at three time points. However, the data cannot be used to construct a complete picture of each child's full exposure to various types of child care from birth to age 4. For example, if during the 48-month wave a parent indicates that their child is not currently enrolled in preschool, there is no way to discern whether the child was in preschool at *any* point since the 24-month wave data collection. A related issue is that a child who attends preschool for the first time at 48 months, and participates for 30 hr a week, will be indistinguishable from one who has been attending for 30 hr starting just after their 24-month assessment. It is therefore not possible to fully explore the issue of preschool exposure using this dataset, although analyses using somewhat cruder measures of exposure (i.e., attended preschool for at least 2 years) are certainly possible.

A second limitation of the study is that it considers only the very short-term impacts of attending preschool. Public investment in early childhood interventions is motivated by the desire to make a meaningful and lasting impact on the life of participants throughout their school years and beyond. It remains to be seen whether the positive effects observed in this study persist as the ECLS–B children continue into elementary school. Data from the final waves of the ECLS–B are not yet released. When they are, it will be possible to examine the link between preschool participation and cognitive outcomes at kindergarten entry.

Unfortunately, the design of the ECLS–B does not allow for tracking of children after school entrance. However, previous studies have shown that the impacts of preschool interventions often dissipate as children progress through school (Karoly et al., 1998; Magnuson et al., 2007). Further, there is some evidence that the extent of this fade out, at least in the case of Head Start, is systematically different for Black and White children. Currie and Thomas (2000) show that although the positive effects of Head Start among Black children disappear rapidly, White children experience long-lasting benefits through adolescence. They attribute these differences to differences in the average quality of schools that Black and White children attend. Ferguson (1998) hypothesizes that universal access to preschool might actually exacerbate gaps between White and Black children if both groups benefit, but the effects dissipate more rapidly among Black children. Understanding the extent to which positive gains from preschool fade and the extent to which this fade-out varies across groups is essential for better understanding the potential of preschool interventions to narrow long-term achievement gaps between groups.

Concluding Remarks

The current study evaluates the impact of preschool participation at age 4 using a large, nationally representative data set and controls for a detailed set of pretreatment characteristics including cognitive measures. The findings add to our understanding of the extent to which preschool interventions could meaningfully narrow socioeconomic and racial achievement gaps. The results echo those from previous studies that find that preschool participation is particularly beneficial for poor children. They demonstrate that, on average, poor children, irrespective of racial and ethnic background, benefit substantially and at about the same rate from preschool participation. The findings also underscore the importance of distinguishing racial differences in preschool effects from socioeconomic differences. They suggest that both poor and nonpoor Black children benefit significantly from preschool participation.

Between 2002 and 2008, the percentage of 4-year-olds enrolled in state preschool programs has grown from 14% to 24% (Barnett et al., 2008). Three states currently provide universal access to preschool, and others states are considering such initiatives. Expanded and universally available preschool programs are likely to narrow achievement gaps only if some subgroups experience larger benefits than others. This study provides encouraging preliminary evidence that both socioeconomic achievement gaps and Black–White achievement gaps could narrow within the context of a universal preschool program.

Movement Planning Reflects Skill Level and Age Changes in Toddlers

Yu-ping Chen

University of Massachusetts

Kerstin Rosander and
Claes von Hofsten
Uppsala University

Kinematic measures of children's reaching were found to reflect stable differences in skill level for planning for future actions. Thirty-five toddlers (18–21 months) were engaged in building block towers (precise task) and in placing blocks into an open container (imprecise task). Sixteen children were retested on the same tasks a year later. Longer deceleration as the hand approached the block for pickup was found in the tower task compared with the imprecise task, indicating planning for the second movement. More skillful toddlers who could build high towers had a longer deceleration phase when placing blocks on the tower than toddlers who built low towers. Kinematic differences between the groups remained a year later when all children could build high towers.

Task demands affect the kinematics of reaching for objects in adults (Marteniuk, MacKenzie, Jeannerod, Athenes, & Dugas, 1987). Reaching slows when the hand approaches an object that will subsequently be picked up and used in a precise way compared with an imprecise way. When young adults were asked to grasp a disk (4 cm in diameter) and then to either fit it into a small well (4.1 cm in diameter) or throw the same disk inside a box (20 cm × 40 cm × 15 cm), the approach movement to pick up the disk during the fitting task was slower, with a longer duration and a longer time spent in the deceleration phase, compared with the throwing task (Marteniuk et al., 1987).

Similar findings have been observed in the healthy elderly (Weir, MacDonald, Mallat, Leavitt, & Roy, 1998) and to some extent in healthy 10.5-month-old infants (Claxton, Keen, & McCarty, 2003). Active healthy elderly slowed the approach phase of their reaching for the object and spent a longer duration in deceleration while completing the fitting task, compared with the throwing task. For infants only two measures, peak speed and average speed, distinguished between the tasks. Like adults, infants reached to pick up a ball more slowly if they were going to fit it into a plastic tube as opposed to subsequently throwing it. Claxton et al. (2003) interpreted their findings as evidence of motor planning for an upcoming task. These studies demonstrate that task demands of the subsequent action affect the kinematics of reaching for objects over a wide age range. Slowness in the approach kinematics has been assumed to reflect the person's intention to engage in a future precision action. This is striking because there was no obvious need to vary the approach with regard to the subsequent movement because the object was the same for both actions.

As would be expected, reaching kinematics differed during the action of completing a precision task, as well as during the approach phase. When young adults were asked to point at a target using their tip of index finger compared with using any part of their hand, reaching was characterized by lower peak velocity and a longer deceleration phase (Wu, Lin, Lin, Chang, & Chen, 2005). Bryden and Roy (1999) asked adults to place a peg into a hole. They varied the diameter of the peg while keeping the peg hole the same so that sometimes it fit snug-

gly and sometimes loosely in order to examine the effect of precision on reaching kinematics. Bryden and Roy also did the reverse: varying the peg hole but keeping the peg the same size. As expected, when the precision requirement increased with either manipulation, kinematic patterns during the action had longer movement time, lower peak velocity, and a longer deceleration phase. Thus, precision demands appear to exert a similar effect on both the approach phase and the manipulation phase.

To our knowledge, no study has examined whether task demands affect reaching kinematics in toddlers. Because toddlers have more reaching experience and better motor control than infants under a year of age, their reaching kinematics should more closely resemble those of adults. We specifically chose tower building as the precision task in this study as it is an activity most of the toddlers enjoy and it requires precision when placing one block on the top of another. Age-related norms of children's ability to construct towers are well established in many standardized assessment tools, such as the Bayley Scale of Infant Development (Bayley, 1969), or the Gesell Developmental Observation (Gesell & Amatruda, 1954). Toddlers of the same age have different levels of performance in tower building. For example, in the Bayley Scale, on average, the 13.8-month-olds (range = 10–19 months) can build a two-level cube tower, 16.7-month-olds (range = 13–21 months) can build a three-level cube tower, and 23-month-olds (range = 17–30 months) can build a six-level cube tower. We know of no study that has reported whether there are any differences in reaching kinematics between the skilled and the less skilled tower-building toddlers, but one would predict that more skilled children would show more mature patterns of movement.

The adult-learning literature describes how different skill levels affect the kinematics of movements in adults (Gentiner, 1983; Larochelle, 1983). The coordination patterns between skilled and less skilled performers were distinguishable in adults (Gentiner, 1983; Larochelle, 1983; Temprado, Della-Grasta, Farrell, & Laurent, 1997). It is difficult to make predictions for young children based on adult performance, but we can hypothesize that differences in the skill with which toddlers can build block towers will be reflected in their reaching kinematics for the precision task. On the other hand, when engaged in imprecise tasks with those same blocks, movement kinematics would not be expected to differ with skill level.

In this study we examined how task demands, skill level, and object size affect the reaching kinematics of a group of typically developing toddlers. Tower building, which required precision, was compared with a "clean-up" task of putting blocks into a large container. In Study 1, we tested within the ages of 18–21 months indicated by the Gesell and Bayley Scale norms to encompass a range of ability in tower building. We hypothesized that all toddlers would (a) slow down their reaching to pick up and move blocks when building a block tower compared with the imprecise task and (b) have different reaching kinematics when manipulating large and small blocks because it is harder to build a tower with small blocks. Furthermore, in order to examine the control strategies of toddlers who were better at the precise task, we compared high- and low-tower builders (a) when building towers and placing blocks in a container and (b) when placing blocks low in the tower versus high in the tower when more care was required. We hypothesized that toddlers who could build a high tower would slow down more in the precision task but not differ on the imprecise task. We also hypothesized that their reaching kinematics would adapt to task difficulty, slowing still further as they placed the final blocks on a tall tower. Finally, in Study 2, we brought back a subset of children a year later to see how their developing motor skills affected reaching kinematics while performing those same tasks. The continuity of skill level in high- and low-tower children was also assessed. Because all children could build a tall tower at the older age, the question was whether any initial kinematic differences would remain.

General Method

Stimuli and Apparatus

The stimuli consisted of ten 2.5-in. wooden blocks, ten 1-in. wooden cubes from the Gesell Scale of Infant Development (Gesell & Amatruda, 1954), and two large open containers with sizes appropriate to block size (30 cm × 21.5 cm × 8.5 cm and 18 cm × 12 cm × 7 cm). Gesell cubes were used rather than Bayley Scale cubes because the former are wooden and the latter are plastic. Because the large blocks were wooden, the small blocks needed to be made of the same material for comparison. The containers were available to children for the imprecise task of placing or throwing blocks into them. (Note: Block size did not systematically affect kinematics or behavior and will not be considered further.)

Hand movements were recorded at 100-Hz sampling rate using two linked banks of cameras from Phoenix System (Phoenix Co., Burnaby, BC, Canada). The two camera banks were placed on either side of the child to record movements of each hand. The camera banks were positioned at a height of about 2 m from the floor and 2 m away from the child. Prior to data collection, the testing area was calibrated by moving a rod with two sensors supplied by the Phoenix Systems through out the testing area. The average root mean square error in the calibration was always < 0.9 mm for each data collection session. One digital camera (Sony, DCR-TRV510, Sony Corporation of USA, New York, NY) with a superimposed timer was placed 45° from the horizontal plane of the toddlers' left-hand side to record behavioral movements. The kinematic data from the Phoenix Systems and video recording were synchronized by time codes placed on both devices during data collection.

Procedure

After obtaining signed informed consent from the parents, toddlers were seated on the lap of their parents at a card table, with the surface around waist height of the toddlers. The experimenter was seated across the table to present the testing stimuli and encourage toddlers to engage in the activities. Two small infrared-emitting sensors (5 mm in diameter) embedded in a Velcro wrist band were placed around each of the toddler wrists to record kinematic data for the Phoenix Systems.

Two tasks (tower building and placing blocks into an open container) and two block sizes (large and small) were presented. The testing sequence was counterbalanced between large and small blocks so that half of the toddlers were presented with large blocks first and the other half with small blocks first. The session always started with the imprecise task to reduce the possible frustration of not being able to build the block tower. At the beginning of each task, the experimenter demonstrated throwing the blocks or the tower-building movements one or two times to encourage toddlers' engagement. For the imprecise task, toddlers were encouraged to grasp a block placed at their right-hand side and then place or throw it into the large container placed at their left-hand side. For the tower-building task, toddlers were encouraged to grasp the block placed at their right-hand side and to build a block tower at their left-hand side as tall as possible. The experimenter always put the first block of the tower on the toddler's left-hand side to mark the tower location. The distance between the blocks to be picked up and the container or the tower was about 20 cm; however, the starting position of the toddler's hand was not constrained. Unlike adult studies in which starting position of the hand is specified, the unconstrained starting position of toddler reaches results in a variable distance between block and hand over trials and children. If the toddler refused to perform the imprecise task, the experimenter moved on to the tower task and later went back to the imprecise task in an attempt to get a sufficient number of usable reaches. Each condition was repeated at least four times or until the toddlers were no longer interested. (See Figure 1 for photograph of child engaged in the tower-building task.)

Data Reduction

Position data were converted into three-dimensional coordinate data using Phoenix system software. All reaches were viewed and scored from the videotapes to determine the beginning and end of a reach. Two types of reaches were scored: the approach phase and the placement phase.

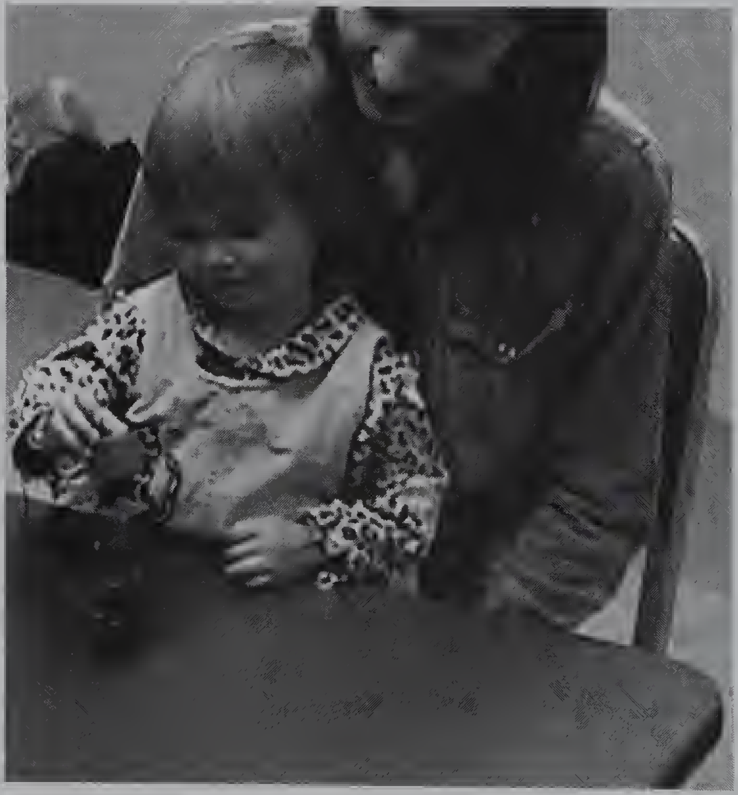

Figure 1. Photograph of a child engaged in the tower-building task using small blocks.

Note. Two small infrared-emitting sensors embedded in a Velcro wrist band were placed around each of the toddler's wrists.

The approach phase began with the first frame that the hand started to move toward the block and ended when the hand contacted the block. The placement phase started with the first frame that the block in hand started to be moved and ended at the first frame when fingers opened to release the block either into the container or on top of the block tower.

A primary observer scored all reaches from the videotape for the onset and end time of the approaching and the placement phases, as well as the tallest level of the tower each toddler could perform during the testing. These times demarcated the Phoenix data so that kinematic measures could be derived from each reach using MATLAB software (Mathworks, Natick, MA). A second observer scored all 310 reaches in 4 toddlers to calculate reliability for onset time of the approach phase (94% agreement), end time of the approach phase (97% agreement), onset time of the placement phase (95% agreement), and end time of the placement phase (78% agreement). Whenever the scored time differed by more than 0.099 s (three frames), the primary and secondary observers met to obtain agreement on the final times used for analyses ($n = 9$ for onset time of the approach phase, $n = 4$ for end time of the approach phase, $n = 9$ for onset time of the placement phase, and $n = 37$ for end time of the placement phase).

Six kinematic measures were derived for the approach and placement phases separately, including movement time (MT, defined as the time from onset to end time of each phase), straightness ratio (SR, defined as the total path length of the hand divided by the shortest distance between hand positions at the start and end frames of the reach), average speed of the reach (MEANV), amplitude of the peak velocity (PV), percentage of movement time to peak velocity (PPV, defined as the time between the start frame to the frame of peak velocity, divided by the movement time), speed at the time of contact (for the approach phase), or release of the block (for the placement phase; ENDV, defined as the speed at the end of the reach).

Toddlers' skill level of tower building was determined by the tallest level of towers they built using the 1-in. blocks from the Gesell Scale. According to the norms for this scale, the mean age of toddlers to build a two-block tower is 12 months, the mean age to build a three-block tower is 18 months, and the mean age of toddlers to build a seven-block tower is 24.0 months. (These norms are comparable with the Bayley Scale norms, which have a mean age of 13.8 months for two-block towers, 16.7 months three-block towers, and 23 months for six-block towers.) We therefore divided our toddlers into three skill levels: (a) high-tower builders who could build a four-block or higher tower, (b) low-tower builders who could build a two- or three-block tower, and (c) no-tower builders who could not build any tower. The reliability for scoring the tallest level of tower between the primary and the second observers were 100%.

For high-tower builders, we used the same criteria of determining toddlers' skill level of tower-building to determine the difficulty of reaches. Reaches during the act of tower building were categorized into difficult reaches (i.e., placing Block 4 or higher) and easy reaches (i.e., placing Block 2 or 3).

Study 1

Participants

Thirty-nine toddlers aged between 18 and 21 months participated in this study. Three were excluded from the analysis because of fussiness and refusing to wear the sensors placed on the hands, and 1 was excluded because of disinterest in the block activities, leaving 35 toddlers (19 males, 16 females; mean age = 19.7 months, *SD* = 1.2 months). The sample was composed of 35 Caucasian, middle-class children. The parents were first contacted by an informational letter describing the study, which was followed by a telephone call to see if they were interested in participating. Each toddler received a T-shirt with the lab logo and a certificate at the end of the testing as our appreciation of participation. All parents or legal guardians of the toddlers signed the informed consents in accordance with the policies of Institutional Review Board of the University of Massachusetts prior to testing.

Results and Discussion

Four children in this study did not build a tower in the small block condition, so their data were excluded from the data analyses, leaving 31 children who provided complete data for reaches in both phases of both tasks. Of those, 15 were in the low-tower group (two- or three-block tower) and 16 were in the high-tower group (four-block tower or higher).

In preliminary analyses, comparisons of the initial distance of the approach and the placement phase revealed a difference between the imprecise and tower tasks. For the approach phase, toddlers' reaches started significantly farther away from the block to be picked up in the imprecise tasks, $F(1, 22) = 13.22$, $p = .001$. The mean distance was 195 mm ($SE = 7$ mm) for the imprecise task and 161 mm ($SE = 5$ mm) for the tower task. For the placement phase, toddlers' reaches also started significantly farther away from the final release point in the imprecise tasks, $F(1, 27) = 25.32$, $p < .001$. The mean distance was 198 mm ($SE = 6$ mm) for the imprecise task and 166 mm ($SE = 4$ mm) for the tower task. Although the experimenter controlled the distance between the blocks and the container or tower, it was impossible to control the starting position and movements of the toddlers' hands. Because the distance the hand traveled could affect kinematic measures, such as MT and PV, we statistically controlled for initial distance as a covariate using mixed regression models to test the differences between tasks, skill level, and block sizes on each kinematic measure using the SAS program version 8.0 (SAS Institute Inc., Cary, NC).

We also examined gender differences for each kinematic measure during approach and placement phases. None of the kinematic measures revealed statistical differences between male and female toddlers (all $ps > .05$).

As noted earlier, the testing session in this study always started with the imprecise task, but 9 of the 31 children who built at least a two-block tower started with the tower task because they initially refused the imprecise task. An analysis of variance (ANOVA) was carried out with order as a main effect. There were no differences in the approach and placement phases for these 9 toddlers who performed the tower task first compared to others who performed the imprecise task first.

In the analyses comparing skill level of groups, only reaches for the approach and placement of Blocks 2 and 3 were used because the low-tower group, by definition, did not contribute reaches beyond this level. The average number of reaches per child during the approach phase was 6.23 ($SD = 5.43$) for the tower task and 10.09 ($SD = 7.62$) for the imprecise task. The average number of reaches per child during the placement phase was 10.49 ($SD = 6.53$) for the tower task and 13.20 ($SD = 8.09$) for the imprecise task. Reaches to blocks placed higher in the stack were analyzed separately for the high-tower group. The data for each kinematic measure were analyzed with a mixed regression model of Task (2) × Block Size (2) × Skill Level (2), with initial distance between hand and object as a covariate for the approach phase data. A similar analysis was performed for the placement phase data, with initial distance between hand and tower or container as the covariate. Table 1 gives the adjusted means and standard errors for all kinematic measures for both phases of both tasks.

Task requirements and kinematic differences. As expected, the degree to which precise movement was required in the task changed the topography of the reach during both the approach and the placement phase. When toddlers approached a block with the intention of later placing it on a tower, peak velocity was reached earlier in the movement, followed by a long deceleration that ended in picking up the block (PPV = 0.42 for tower and 0.50 for throwing). Statistically this was expressed as a main effect of task in the PPV measure, $F(1, 22) = 4.31$, $p < .05$, Cohen's $f = 0.33$. A lower PPV value indicates that the hand spent a longer portion of the reach in slowing its approach to grasp the block. The approach in the tower task also had a shorter movement time than the throwing task, $F(1, 22) = 7.30$, $p < .01$, Cohen's $f = 0.45$ (average MT for tower task was 0.97 s and for throwing was 1.16 s). The finding for movement time was unique in that it is the only measure significant in the opposite

Table 1

Adjusted Means and Standard Errors for All Kinematic Measures in the Precise and the Imprecise Tasks in the Approach Phase and the Placement Phase in Study 1

	Tower (precise)	Container (imprecise)
Approach phase		
Movement time (s)	0.97 (0.05)	1.16 (0.05)**
Straightness ratio	1.81 (0.15)	1.98 (0.15)
Average speed of the reach (mm/s)	319.84 (13.81)	304.50 (13.80)
Amplitude of peak velocity (mm/s)	684.91 (43.77)	615.59 (43.75)
Point of peak velocity	0.42 (0.02)	0.50 (0.02)*
End speed (mm/s)	210.12 (17.66)	245.30 (17.64)
Placement phase		
Movement time (s)	1.80 (0.07)	1.02 (0.07)**
Straightness ratio	1.67 (0.08)	1.72 (0.08)

End speed (mm/s)	79.26 (28.56)	383.85 (28.53)**

*$p < .05$. **$p < .01$.

direction to that predicted. There is no ready explanation for this, and as reported next in the placement phase movement time was significant in the expected direction, with the tower task having a longer placement movement.

Once the block was grasped, the movement to place it on a tower was greatly slowed compared with a throwing movement into the container. Several velocity measures reflected this difference: Tower building had a lower average velocity, $F(1, 27) = 86.24$, $p < .0001$, Cohen's $f = 1.66$; a lower peak velocity, $F(1, 27) = 11.89$, $p < .002$, Cohen's $f = 0.59$; a lower contact or end velocity, $F(1, 27) = 53.32$, $p < .0001$, Cohen's $f = 1.30$; and as in the approach phase, peak velocity was reached earlier in the movement, $F(1, 27) = 83.41$, $p < .0001$, Cohen's $f = 1.63$ for PPV. Duration of movement was also longer for tower building, $F(1, 27) = 74.07$, $p < .001$, Cohen's $f = 1.54$, as would be expected from the slower velocity measures. Figure 2a

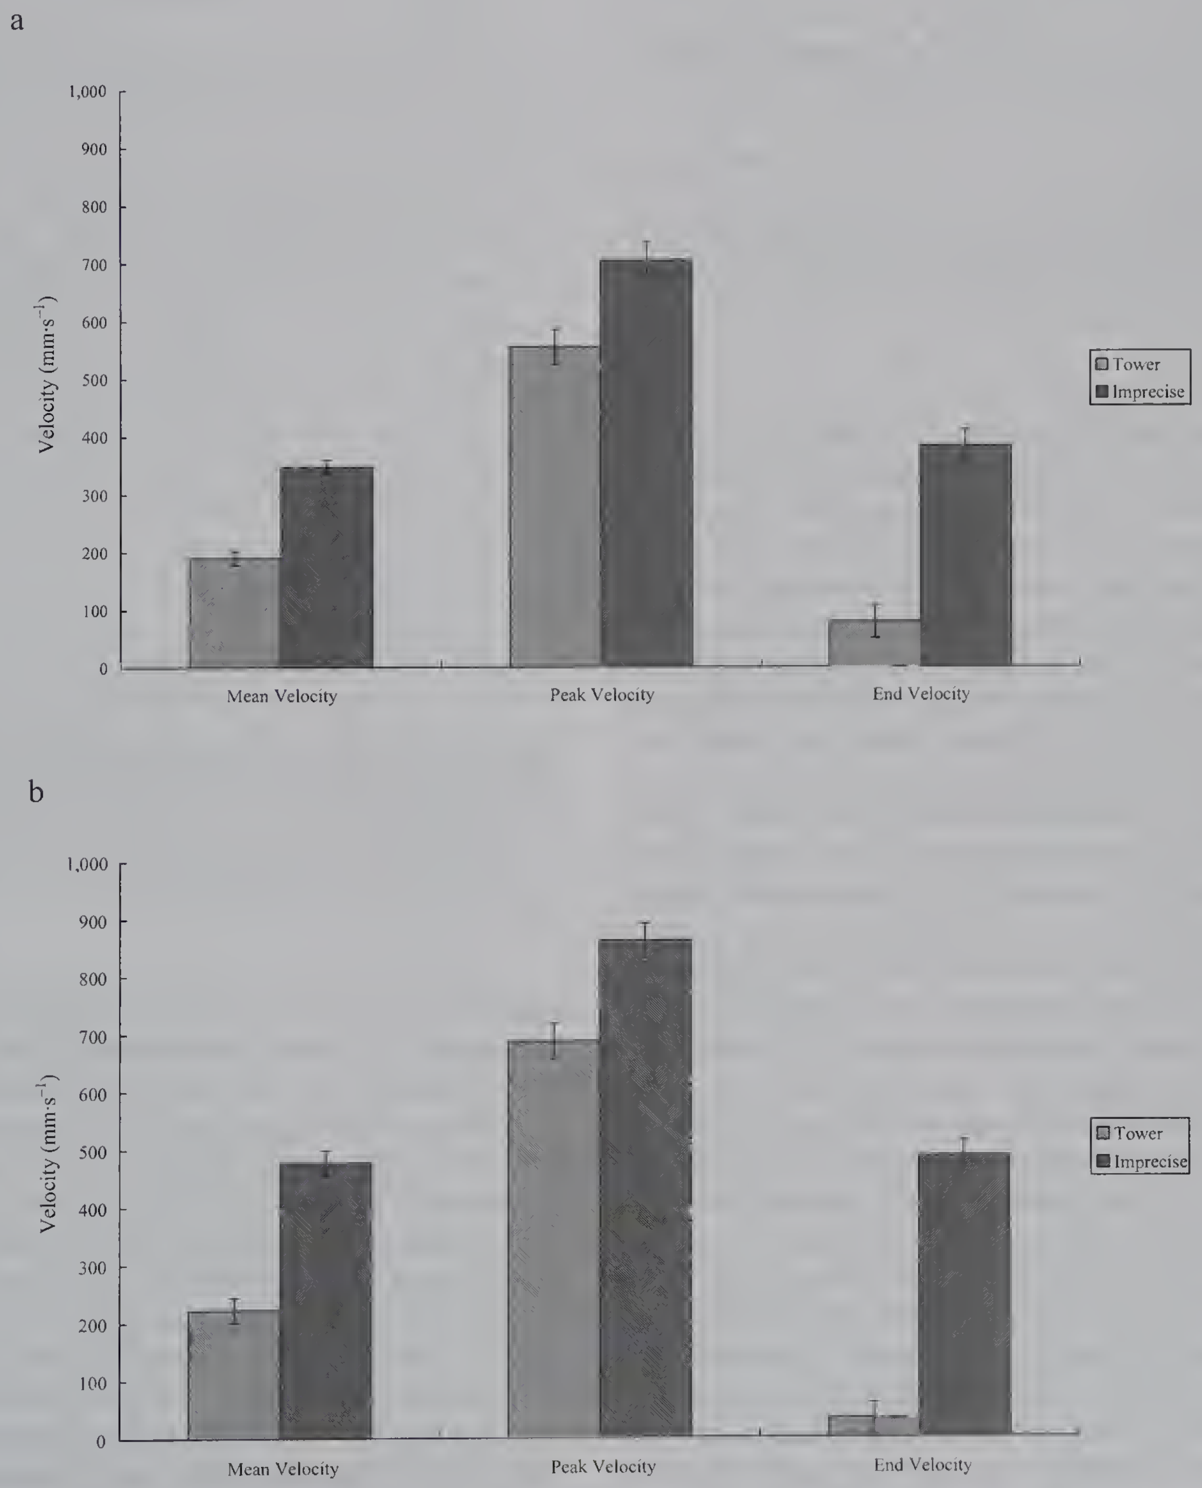

Figure 2. Three velocity measures for the placement phase are displayed for the children at 20 months in Study 1 (a) and a year later in Study 2 (b).
Note. There was consistent slowing of the hand when engaged in a precision task.

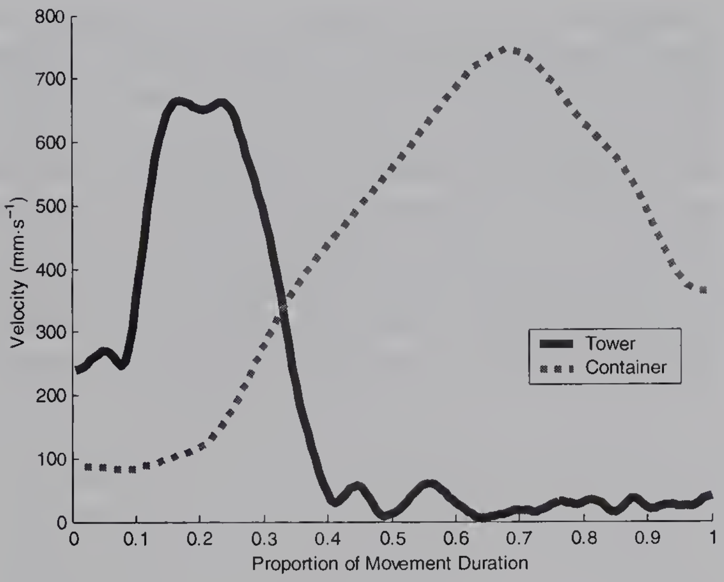

Figure 3. The velocity profile on a single trial from the same child on each task.
Note. This child's hand reached peak velocity earlier when placing a block on the top of the tower compared with throwing a block into the container. Reaches were normalized to the movement time.

displays the group averages for velocity measures, MEANV, PV, and ENDV, showing the consistent slowing of the hand when engaged in a precision task. Figure 3 shows the velocity profile for a single trial from a child on each task, illustrating how the PPV measure varied with the task. This child's hand reached peak velocity earlier, allowing more time for small corrective movements when placing a block on the top of the tower compared with throwing a block into the container.

Skill-level differences in reaching kinematics. Once again, the point of reaching peak velocity in the movement (PPV) proved to be an extremely sensitive measure, $F(1, 27) = 5.28$, $p < .03$, Cohen's $f = 0.37$ (mean PPV was 0.43 for the high-tower group and 0.50 for the low-tower group). The PPV measure is notable because when PV was reached early in the movement, this was followed by a lengthy deceleration as the hand approached the moment where the block was released. A long controlled deceleration reflects good control over the hand movement and would be expected in a skilled performer. Figure 4a shows velocity of a single reach for a high-tower child and a low-tower child when placing a block on a stack. Note the long deceleration limb as the hand approached the point of release for the high-tower child. Although end velocity and average velocity did not differ for high- versus low-tower children, the topography of the reach differed dramatically as shown in Figure 4. We expected to find, but did not, an interaction of skill level with task precision. That is, high-tower builders were expected to move more slowly than low-tower builders when building towers but not when placing blocks into a container, but the PPV difference was still evident when throwing (see Figure 4b). In summary, skill-level differences were reliable only for the placement phase, and the earlier PPV was present in both tasks for the high-tower group.

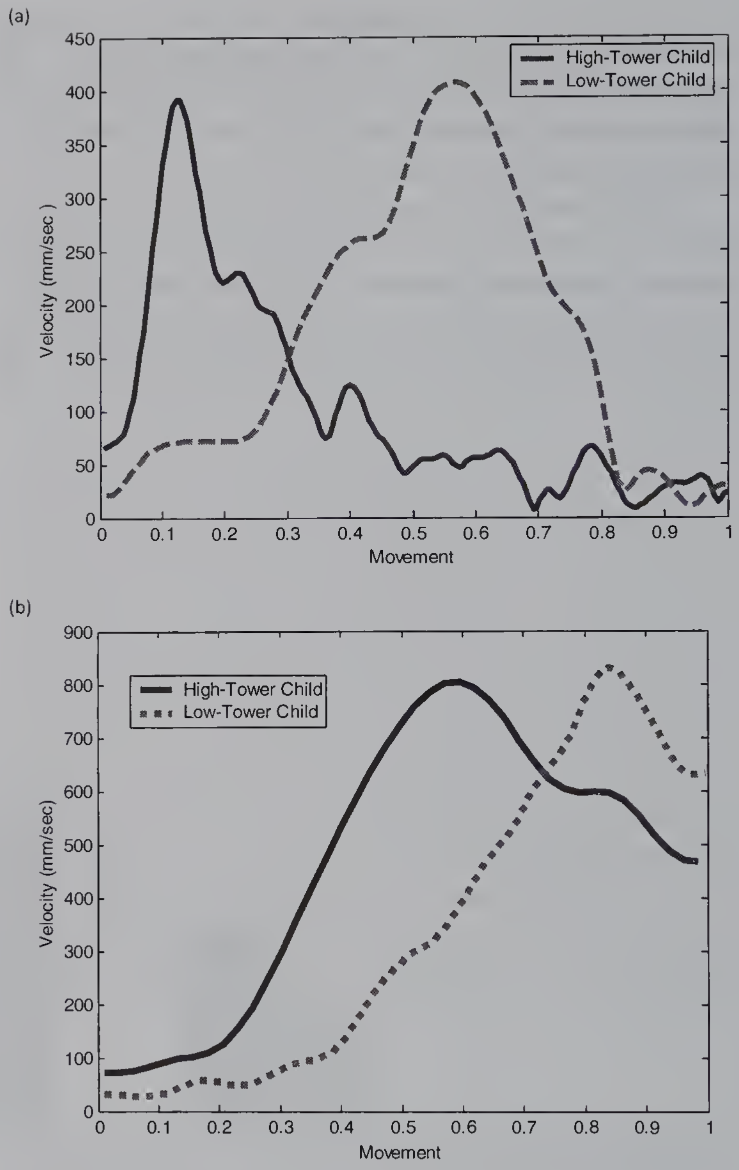

Figure 4. The velocity profile on a single trial of the (a) tower-building task and (b) imprecise task for a high-tower child and a low-tower child.
Note. The hand of the high-tower child reached peak velocity earlier in both cases compared with the low-tower child. Reaches were normalized to the movement time.

The slowed-down approach toward the tower seems to be a necessary component of successfully placing blocks on a tall tower. We hypothesized that the kinematics of the movement toward the tower would change as the stack grew higher. An analysis was carried out on the kinematics of the high-tower group when they were placing blocks low in the tower (under 4 blocks) versus high in the tower (4+ blocks). Contrary to our expectations, children did not change their strategy while building the tower. High-tower children showed greater deceleration when approaching the tower at all levels. Perhaps they represented the functional act of placing a block on the tower as a unit to be repeated, without regard for the changing level of the tower.

Study 2

The purpose of Study 2 was to assess the kinematics of reaching and manipulating blocks a year later in the same tasks that children were given at 18–21 months of age. The issue of greatest interest was whether the skill-level differences apparent at the earlier age would persist a year later when all children could build tall towers. Earlier differences might be transitory if caution in placing blocks on the tower was produced because children whom we designated as high-tower got tested just at the point of learning to master a new skill. In other words, the difference between high- and low-tower children was due to catching some children while they were in the process of achieving new motor control in building block towers. On the other hand, if their kinematics at 18–21 months were indicative of some more general motor skill, the high-tower children would be expected to move with greater skill a year later. That is, if their greater skill at 18 months was a stable characteristic, then group differences would be expected to remain.

Participants

Seventeen of the 31 children who could build at least two-level block towers in Study 1 returned to participate in Study 2. One of the 17 children who was diagnosed as having a developmental delay with recurrent seizure attacks was excluded from the final analysis, leaving 16 children (10 males and 6 females) aged 30–37 months (mean age = 33.98 months, *SD* = 2.37 months). Among the 16 children, 9 could build towers of four or more blocks in their first visit (high-tower group) and 7 could build towers of two or three blocks (low-tower group). All parents who still lived in the area were again contacted by an informational letter describing the study, which was followed by telephone call to see if they were interested in returning to the laboratory. Each child received a book and a certificate as tokens of our appreciation for their participation. All parents or legal guardians of the toddlers signed the informed consents in accordance with the policies of Institutional Review Board of the University of Massachusetts prior to testing.

Results and Discussion

In preliminary analyses, comparisons of the initial distance of the approach and placement phase again revealed a difference between the imprecise and tower tasks. As in Study 1, for the approach phase children's reaches began significantly farther away from the block to be picked up in the imprecise tasks, $F(1, 15) = 25.72$, $p < .0001$. The mean distance was 241 mm (*SE* = 9 mm) for the imprecise task and 188 mm (*SE* = 9 mm) for the tower task. For the placement phase, children's reaches also started significantly farther away from the final release point in the imprecise tasks, $F(1, 15) = 5.00$, $p < .04$. The mean distance was 241 mm (*SE* = 9 mm) for the imprecise task and 212 mm (*SE* = 9 mm) for the tower task. Because the distance the hand traveled could affect kinematic measures, such as MT and PV, we statistically controlled for initial distance as a covariate using mixed regression models to test the differences between tasks, skill level, and block size on each kinematic measure using the SAS program version 8.0 (SAS Institute Inc., Cary, NC).

Regardless of their skill level in Study 1, all children, now between 2.5 and 3.0 years of age, could build tall towers. The mean number of blocks in the stack for the high-tower group was 7.71 and for the low-tower group, 7.11. All reaches used to build towers were averaged and used to represent the tower task. The average number of reaches per child during the approach phase was 9.25 (*SD* = 4.88) for the tower task and 28.88 (*SD* = 9.07) for the imprecise task. The average number of reaches per child during the placement phase was 11.25 (*SD* = 3.89) for the tower task and 29.56 (*SD* = 10.96) for the imprecise task. The data for each kinematic measure were analyzed with a mixed regression model of Task (2) × Block Size (2) × Skill Level (2), with initial distance between hand and object as a covariate for the approach phase data. A similar analysis was performed for the placement phase data, with initial distance between hand and tower or container as the covariate. Table 2 gives the adjusted means and standard errors for all kinematic measures for both phases of both tasks.

Table 2

**$p < .01$.

Task and skill-level differences a year later. No task differences emerged during the approach phase for these children. Once the block was grasped, however, the movement to place it on a tower was greatly slowed compared to throwing it into the container, similar to findings of Study 1. Several velocity measures reflected this difference: Compared with the throwing task, tower building had a lower average velocity, $F(1, 14) = 138.70$, $p < .0001$, Cohen's $f = 2.93$; a lower peak velocity, $F(1, 14) = 40.98$, $p < .0001$, Cohen's $f = 1.58$; and a lower end velocity, $F(1, 14) = 173.2$, $p < .0001$, Cohen's $f = 3.28$. Peak velocity was reached earlier in the movement, $F(1, 14) = 369.38$, $p < .0001$, Cohen's $f = 4.80$. See Figure 2b for a display of these task differences. Duration of movement was also longer for tower building, $F(1, 14) = 135.84$, $p < .0001$, Cohen's $f = 2.90$, as would be expected from the slower velocity measures.

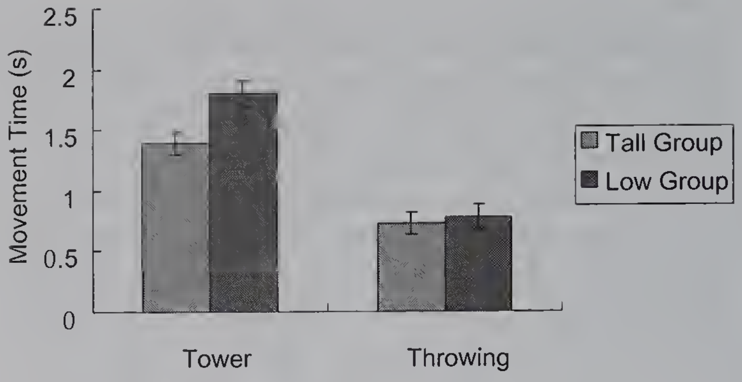

Figure 5. Movement time in the high-tower group and the low-tower group in precise and imprecise tasks in Study 2.

The groups based on skill level, as determined by their tower building during the earlier visit, still had kinematic differences when building towers. Although both groups built equally tall towers in this second visit, the hand movements of the high-tower group were faster. They had a shorter movement time between grasping the block and placing it on the stack but no group difference when throwing blocks into the container (see Figure 5). Statistically this was shown by a Task × Group interaction for MT, $F(1, 14) = 7.44$, $p < .02$, Cohen's $f = 0.63$. In addition, the high-tower group reached peak velocity later in the reach, leaving less time for the hand to decelerate as the block was released from the fingers, $F(1, 14) = 6.91$, $p < .02$, Cohen's $f = 0.61$. This resulted in a higher ENDV for this group, $F(1, 14) = 4.41$, $p < .05$, Cohen's $f = 0.46$. Being able to accomplish a precision task at a higher speed reflects greater mastery in motor control for this group. In Table 3, we list all reliable differences between high- and low-tower groups. The table also lists the PPV for the earlier test session because it is of interest to compare the absolute numbers for this important measure across ages.

Continuity within each child was tested by correlating their kinematic measures at the younger age with those same measures at the older age. All significant correlations were specific to the throwing task. MEANV was significant ($rs = .501$ and $.603$ for approach and placement phases, respectively), and peak velocity was reliable for placement ($r = .53$). Movement time and straightness ratio of the approach phase had significant correlations ($rs = .56$ and $.58$ for MT and SR, respectively). MEANV, MT, and SR during approach were the same three variables that showed consistent improvement over age (see next section and Table 4), and these correlations suggest that the maturing arm/hand control between 2 and 3 years of age has stability within individual children.

Developmental change in reaching kinematics between 20 and 30 months of age. Because the same children were tested about a year apart, developmental changes in reaching kinematics could be compared. Between the 2nd and 3rd years of life manual skill is advancing rapidly, shown by

children's mastery of fine motor control over fingers and arms to perform precision movements. In order to make comparisons between the first and second sessions, the initial distance the hand traveled during the approach and placement phases had to be taken into account. This distance was shorter when the children were younger, as would be expected because greater arm length and hand size would extend the length of reaches at the older age. For the approach phase, the mean distance traveled was 183.22 mm (*SD* = 38.17 mm) at the younger age and 195.06 mm (*SD* = 55.84 mm) when children were retested. Because the distance the hand traveled could affect kinematic measures, we statistically controlled for initial distance as a covariate using mixed regression models to test the age differences for each kinematic measure using the SAS program version 8.0 (SAS Institute Inc., Cary, NC).

To test for change in movement kinematics between the 2nd and 3rd years of life an ANOVA on Age × Task × Group was performed for approach and placement phases. When children's hands approached a block, the older children had a shorter movement duration, MT: $F(1, 14) = 49.51$, $p < .0001$, Cohen's $f = 1.74$; reaches were straighter, SR: $F(1, 14) = 14.06$, $p < .01$, Cohen's $f = 0.90$; and had a higher average velocity, MEANV: $F(1, 14) = 37.52$, $p < .0001$, Cohen's $f = 1.51$. Once the block was grasped, the older children again took less time to place a block on top of the tower or throw it into a container, MT: $F(1, 14) = 5.58$, $p < .04$, Cohen's $f = 0.54$; they had straighter movements toward the target, SR: $F(1, 14) = 7.86$, $p < .02$, Cohen's $f = 0.65$; and a longer deceleration phase at the end of the reach, PPV: $F(1, 14) = 6.97$, $p < .02$, Cohen's $f = 0.61$. See Table 4 for adjusted means and standard errors for these kinematic measures at both ages. In general, as children approached 3 years of age, their reaches were faster and more efficient in grasping and manipulating the blocks.

General Discussion

Building a tower of blocks is a typical activity of children around 18–24 months of age. It reflects their ability to form a goal and pursue it by repeatedly executing sequential actions. The ability to link perceptual information (in our case shape and size of blocks, height of tower) with the proper motor actions suggests that an overarching goal governed the entire sequence. We examined the kinematics of the approach phase to grasp a block and then the movement to place the block on the tower. Both phases were compared to a more casual task of picking up blocks to put them into a large open container. The approach phase kinematics were expected to differ if children were thinking ahead to their goal after they grasped the block, whereas the kinematics of placement were assumed to reflect the care with which children positioned the block for release (Johnson-Frey, McCarty, & Keen, 2004). This two-stage task of first grasping then manipulating the blocks offers a means of assessing how far ahead intentional actions are planned. Johnson-Frey et al. (2004) had adults reach for a block and subsequently lift and hold it, or transport it to a new location. When adults were anticipating a transport movement, the initial reach-to-grasp duration was affected. The authors concluded that the approach phase was not planned in isolation but was represented in the complete action sequence, including future movements once the block was in hand. Our data show that toddlers' reach-to-grasp actions also indicate planning of the entire sequence rather than executing movements in isolation.

For the approach phase, we found that toddlers reached for blocks differently depending on the task they intended to subsequently perform. In adults, this difference shows up for many kinematic measures, such as total movement time, average speed, peak speed, and when peak speed is reached (Johnson-Frey et al., 2004; Marteniuk et al., 1987), but only the timing of peak speed and the movement time were reliable for toddlers. It was expected that average and peak speed would be lower for the precision task as this was found for infants (Claxton et al., 2003) as well as for adults. Adults and infants had highly similar tasks: Pick up an object and either fit it into a tight hole or throw it into a container. Toddlers may not have viewed the tower-building versus "clean-up" tasks as differing very much in precision compared with the previous "fit it or throw it" tasks. Future studies with toddlers should test them on tasks more similar to what adults did. Nevertheless, as predicted from the adult data, peak speed was reached earlier in the approach for tower building. This task difference suggests that toddlers are beginning to plan sequential stages of the action from the very beginning of movement. Although there is no obvious need for the hand to slow in its approach to pick up the block, the intention to subsequently perform a precision task appears to affect hand speed in the first stage of this two-stage action. We conclude that for this age PPV is a more sensitive measure of the added care used when approaching blocks to be used in building a tower.

In the placement phase, toddlers exhibited numerous kinematic differences between the two tasks. When building a tower, all three measures of velocity (peak, average, and contact velocity) reflected slowing of the hand throughout the movement as blocks were lifted and added to the stack, compared with being lifted and released into an open container. Thus, children appeared to hold their goal in mind when performing sequential actions involving several items, and exhibited lower velocity when engaged in a precision task just as adults do (Berthier, Clifton, Gullapalli, McCall, & Robin, 1996; Bryden & Roy, 1999; Johnson-Frey et al., 2004; Wu et al., 2005).

The timing of peak velocity proved to be more sensitive to task demands and to skill-level differences than other kinematic measures for this age group. Why should this be so? Presumably the point at which peak speed is reached, or PPV, reflects how control demands are exercised during the movement. The beginning of a movement is primarily devoted to transporting the limb whereas the later parts are controlling the final approach and securing an appropriate grasp in the approach phase and release in the placement phase. The later parts are more dependent on visual feedback for adjusting the details of the movement. In infants' reaching, movements are produced in a series of submovements (movement units), each with a distinct acceleration and deceleration phase (von Hofsten, 1979, 1991). As infants come to master reaching, the largest unit will be situated at the beginning of the movement with one or several smaller units following toward the end. The large unit at the beginning is devoted to the transport whereas the smaller units are devoted to the grasp or release. At the end of the movement, the object and the reaching hand are simultaneously visible and control can therefore be quite precise. If precision demands are high, peak speed will occur earlier to allow time for precise control. On the other hand, if precision demands are low, peak speed will occur later because the movement before peak speed is reached is focused on transport with less need for slowed down movement.

As noted earlier, peak speed was reached earlier in the precise task and the hand noticeably slowed for the final approach. Although all children displayed this pattern, it was amplified in children who were more skilled at tower building. The high-tower group reached peak speed earlier than the less skilled group when they were initially learning to build a tower. Although their approach to pick up the blocks did not differ, the high-tower children had a more exaggerated deceleration as they placed blocks on the stack. We interpreted this to mean that these children employed the same strategy that adults do when engaged in a precision task, namely, reach peak speed early in the movement in order to slow down before reaching the point where greatest control is needed. For adults, this pattern is shown when picking up a very small object (Berthier et al., 1996), or placing an object into a tight-fitting space (Marteniuk et al., 1987). In this study this same pattern appeared in highly skilled children, suggesting that they realized that placing a block on a tower required care in keeping the entire stack balanced.

Unexpectedly, toddlers who were more skilled also showed this pattern of reaching peak velocity early when releasing blocks into the container when there was no need for extra care. Children of this age who can construct high block towers have probably achieved this skill recently, according to the Bayley norms. We propose that in performing this new skill, the care and attention it required spilled over into the imprecise task that involved the very same blocks (Boudreau & Bushnell, 2000). We suggest that children who have recently acquired the ability to construct tall towers adopted similar movement characteristics for manipulating the blocks in any task. The fact that the same blocks were used in both tasks may have facilitated this tendency. As children become older, building block towers is less challenging and their manipulation kinematics would be expected to differ with task difficulty. When retested a year later, the high-tower group still had kinematic differences from the low-tower group when building a tower but not when placing blocks into an open container.

As toddlers, the high-tower children moved more slowly than low-tower children as they placed blocks on a tower, but a year later they moved more quickly. This change appears to reflect an evolution in skill of tower building. When first learning to successfully balance several blocks in a tower, going slowly is associated with better success. Once mastery is achieved, these children show their superior motor control by going faster, just as highly skilled drivers or skiers can go faster than those with less skill. The fact that throwing velocity did not differ for the groups is evidence that the high-tower children do not move faster in general, but only in the precision task. It would be interesting to have tested other precision tasks because we do not know if their skill was specific to tower-building or was characteristic of their approach to precision tasks in general.

We expected that greater maturity in manual skills would be evident in many kinematic measures when a subset of children from the original study was brought back a year later. The same pattern of task differences prevailed at both ages: Average velocity, peak velocity, and velocity at contact were lower when building a tower than when throwing blocks into a container, and peak velocity was reached earlier in the movement. Within this similar velocity profile, age differences emerged. Reaches at the older age had a faster average velocity as the hand approached the object, and movements had straighter trajectories and shorter durations for both approach and placement phases. Moving faster and straighter toward one's goal in both phases of movement is exactly the expected result of greater motor maturity and would be predicted from others' findings (Contreras-Vidal, 2006; Olivier & Bard, 2000). Konczak and Dichgans (1997) found similar changes in a longitudinal sample of children tested between 5 months and 3 years of age. The task in Konczak and Dichgans was a simple reach for an object held within the child's reach at his or her shoulder height; there was no placement phase in this study. They reported progressive straightening of the path, and increasing peak velocity, with reaches approaching the stereotypic adult pattern of arm kinematics by the 3rd year of life. Of special interest is their finding that the timing of peak velocity moves earlier in the reach, just as in our data, with greater maturity. Task difficulty was not manipulated in this study, but Carrico and Berthier (2008) did test 15-month-olds in the approach phase of reaching for big and small objects. The small object required a pincer grip. Their results mirror ours in several ways. The approach for pickup of the smaller object (a Cheerio) had slower average speed, longer movement time, and peak velocity was reached earlier in the movement, compared with the approach for the larger object (rubber ball).

The change in kinematic measures over age allows us to distinguish two factors included in the development of a skill. The first is about mastering precision requirements, an important aspect of which is allocating relatively more time to visual control of the final part of the movement. When the children in the low-tower group had mastered building a high block tower a year later, they showed very early PPV, the signature measure for extended time at the end of the reach. A second factor included in skill development is making the action more efficient. This includes shorter movement duration, straighter trajectories, and higher average velocity which all children showed when retested a year later. Most striking in the high-tower children a year later, PPV moved later in the reach so that the hand was moving faster when placing blocks on the stack. This higher velocity when performing a precision task reflects greater efficiency for this group.

In summary, kinematic measures of toddlers' performance yielded insight into how they approach and execute tasks varying in difficulty. In particular, the timing of peak speed in relation to the endpoint of the movement was sensitive to children's level of skill and to task demands. Reaching peak velocity earlier in the movement in demanding tasks gives rise to a longer period of deceleration and thus better visual control before the hand arrives at the moment of either contacting the block in the approach phase or releasing it in the placement phase. This pattern was evident at both ages when children reached for a block when the upcoming action required precision and balance. Not surprisingly, this same kinematic pattern was demonstrated during the actual placement of the block on the tower, compared with transferring it to a container. Finally, the sensitivity of this movement timing extended to differentiating among children of different skill levels, a difference that remained stable over 1 year between test sessions. By using two-stage tasks that involved sequential movements, we demonstrated that toddlers engaged in movement planning beyond the available perceptual information and incorporated the final goal of the entire sequence into that planning.

Comprehension of Infrequent Subject–Verb Agreement Forms: Evidence From French-Learning Children

Géraldine Legendre

Louise Goyet and Thierry Nazzi
Université Paris Descartes

Two comprehension experiments were conducted to investigate whether young French-learning children ($N = 76$) are able to use a single number cue in subject–verb agreement contexts and match a visually dynamic scene with a corresponding verbal stimulus. Results from both preferential looking and pointing demonstrated significant comprehension in 30-month-olds with no preference for either singular or plural. These results challenge previous claims made on the basis of English and Spanish that comprehension of subject–verb agreement expressed as a bound morpheme is late, around 5 years of age (V. A. Johnson, J. G. de Villiers, & H. N. Seymour, 2005; A.-T. Pérez-Leroux, 2005). Properties of the adult input were also analyzed. Possible implications for theories of syntactic acquisition are discussed.

Many languages encode a distinction between singular and plural reference, and do so in a variety of ways. This distinction is sometimes encoded redundantly, resulting in grammatical agreement. In English, for example, the number of a referent noun is typically encoded in a determiner entering a dependency with presence versus absence of an –*s* morpheme on the noun: *A boy* (singular) versus *Some boys* (plural). When such nouns occur in subject position they enter a dependency with a verb and the number of the referent noun is also reflected on the verb; however, presence of an –*s* morpheme on the verb marks singular while its absence marks plural: *A boy jumps* versus *Some boys jump*. The relation between the –*s* morpheme and the number category across agreeing constituents is therefore, not a simple one. It is further complicated by the fact that the –*s* morpheme has three phonological realizations, depending on properties of the preceding segment: /əz/ after voiced and voiceless consonants corresponding to segments like ''s,'' ''z,'' ''ch,'' and ''j'' (e.g., *buzzes*), /z/ after vowels and remaining voiced consonants (e.g., *goes*, *jogs*), and /s/ after remaining voiceless consonants (e.g., *jumps*). Despite its phonological variation, –*s* is highly regular in the language because it applies to all verbs, apart from modals (e.g., *can*, *may*, etc.) and auxiliaries which involve additional phonological changes to the roots/stems (e.g., singular *has*, *does*, *is* vs. plural *have*, *do*, and *are*).

The task for a child acquiring any language with an agreement system is at least twofold: She must acquire the expression of number distinctions on nouns and verbs and the principle of agreement across syntactic categories and functions (e.g., subject) that holds in her language. Prerequisites appear to be in place by age 2. For example, the prerequisite category of ''noun'' is supported by studies based on productivity of use of appropriate morphemes (Tomasello & Olguin, 1993) and that of

''verb'' by studies on novel verb learning (Bernal, Lidz, Millotte, & Christophe, 2007). Asymmetrical omission in production indicates that 2-year-olds already distinguish a category of ''subject'' (Valian & Aubry, 2005). Even 17-month-olds show sensitivity to word order suggestive of a subject category in a preferential looking experiment, correctly interpreting the subject in ''Where's Big Bird tickling Cookie Monster?'' by picking the video of Big Bird tickling Cookie Monster, not Cookie Monster tickling Big Bird (Hirsh-Pasek & Golinkoff, 1996).

Several studies have explored children's comprehension and production of subject–verb agreement. First, studies of language production fail to find evidence that 2-year-olds have knowledge of subject–verb agreement. The first multiword utterances spontaneously produced by young children acquiring English do not exhibit its systematic use. Mastery of third-person singular agreement (defined as 90% of use in obligatory contexts) takes place between the ages of 26 and 46 months (Brown, 1973; De Villiers & de Villiers, 1973). In a sentence completion task with nonce verbs requiring the suffix /əz/ (e.g., *nazzes*), even 7-year-olds were shown to have difficulty producing this agreement, succeeding only about 48% of the time (Berko, 1958). In another study comparing the three phonological instantiations of the –*s* morpheme in English, /z/ was found to be the first one to be productively used for marking plural in nouns in an elicitation task, at the age of 6 (Anisfeld & Tucker, 1967). Overall, these production studies show poor performance levels that, moreover, appear to be sensitive to the task used (elicited vs. spontaneous production).

Second, subject–verb agreement has been evaluated using tests of language comprehension, which only found evidence of emergence late in acquisition (Johnson et al., 2005). In a picture selection task using auditory stimuli designed to phonologically mask the number on the noun by using verbs beginning in *s*– such that the child would have to rely on the verbal marking to provide a correct answer, they found that 5- and 6-year-olds, but not 3- and 4-year-olds, were able to select appropriate pictures when hearing *The duck swims in the pond* or *The ducks swim in the pond*. In every age group tested, accuracy was higher for singular –*s* than for plural (null morpheme). The study was replicated in (Caribbean) Spanish, with similar results (Pérez-Leroux, 2005). In that language the pronominal subject is characteristically omitted with the consequence that plural number of the subject may be solely encoded as a suffixal –*n* on the verb (e.g., singular *Nada en el charco* ''[It] swims in the pond'' vs. plural *Nadan en el charco* ''[They] swim in the pond''). The pattern is completely regular in the language and is the same in all varieties of Spanish. Three- to 4½-year-olds performed at chance level in both singular and plural conditions. Older children (4;8–6; 6-year-olds) performed at chance level in the singular condition (null morpheme) but selected the matching picture 67% of the time in the plural condition (–*n*). While the results for Spanish- and English-learning children showed a similar pattern of no comprehension under the age of 4 and similar accuracy level (60%–70%) for children aged 5 and 6, their accuracy level with regard to number was the opposite in the two languages. This was interpreted by Pérez-Leroux (2005) as evidence that children were in fact sensitive to *overt* marking (–*s* on third singular verbs in English, –*n* on third plural verbs in Spanish).

The conclusion of a late emergence of subject–verb comprehension based on Pérez-Leroux's (2005) results is, however, challenged by an independent claim that Spanish-learning children show a preference for singular marking (Childers, Fernandez, Echols, & Tomasello, 2001). In a pointing task using colored drawings of a girl or two children performing actions of walking, singing, sleeping, running, etc., 36-month-old (but not 30-month-old) Chilean Spanish-learning children showed a significant preference for third-person singular auxiliary forms (e.g., *Está corriendo* ''is running'') over plural forms (e.g., *Están corriendo* ''are running''). A trend toward significance in the same direction was found with lexical verbs (e.g., singular *Come los sandwiches* ''eats the sandwiches'' vs. plural *Comen* ''eat''). A study of child-directed speech in Guatemalan Spanish by a subset of the authors is mentioned as evidence that there is a disproportionate number of third-person singular forms in Spanish input to young children, which may explain the bias for singular forms in the experimental results.

Another challenge to the claim of late comprehension of subject–verb agreement comes from a study originally designed to explore comprehension of number marking rather than agreement per se, but suggesting that young children are particularly sensitive to verbal marking (Kouider, Halberda, Wood, & Carey, 2006). In that preferential looking study, 24-month-olds (but not 20-month-olds) looked longer to the matching screen when they heard audio stimuli with several markers of number which included verbal marking (e.g., *There* **are** *some blickets, There* **is a** *blicket*). When only one nominal cue was provided (e.g., *Look at the blickets*, *Look at the blicket*) only 36-month-olds succeeded at the matching task. Detailed looking-time analyses suggested that the most important cue was the distinctive auxiliary (*are* vs. *is*). These results were replicated with familiar nouns using a manual search paradigm and interpreted as evidence that lexical distinctions (*is* vs. *are*) are easier to acquire than bound morphology (*–s*) because the auxiliaries are more salient than a single bound morpheme (Wood, Kouider, & Carey, 2009). They are also more frequent than *–s* marking on a verb in English. Indeed, relative frequencies in the adult input based on a study of two corpora (Nina: 2,835 utterances, Suppes, 1974; Naomi: 705 utterances, Sachs, 1983) reveal that *is* occurs in 26% of adult utterances versus 7% for *–s* (Zaroukian, 2009).

Third, subject–verb agreement was also evaluated through preference studies in younger children given that absence of comprehension does not preclude awareness of agreement. Nineteen-month-olds acquiring English revealed a sensitivity to grammatical subject–verb agreement in *–s* in a headturn preference study, based on grammatical stimuli like *The boy bakes bread* and *The boys bake bread* versus ungrammatical **The boy bake bread* (Soderstrom, 2002; Soderstrom, Wexler, & Jusczyk, 2002). However, these young children were unable to distinguish grammatical from ungrammatical double marking on noun and verb (**The boys bakes bread*) and double verbal marking (**The boy does bakes bread*). This is indicative of some sensitivity to the grammatically appropriate number of *–s* morphemes as well as their placement, hence to the English grammar, rather than a mere sensitivity to and perceptual preference for inflected verbs over uninflected ones (Soderstrom, 2008).

Seeking to tease apart sensitivity to marking from sensitivity to word order as well as the role of lexical knowledge and function words, Soderstrom, While, Conwell, and Morgan (2007) tested young children' ability to track *–s* marking (e.g., verbal as in *The baker bakes bread* or nominal as in *The bakers bake bread*) in passages involving six highly familiar nouns and verbs while manipulating the position of these content words. They found that 16-month-olds were sensitive to grammatically appropriate placement of *–s* on highly familiar nouns and verbs when adjacent to function words (e.g., auxiliaries, prepositions, and determiners). Their study confirms the crucial role played by function words in children' initial formation of grammatical knowledge (Höhle & Weissenborn, 2003; Shady, 1996; Shi, Marquis, & Gauthier, 2006; Shi, Werker, & Cutler, 2006) and provides evidence of the facilitating role played by known content words.

Overall, these last studies suggest that while an early sensitivity to the presence of morphemes encoding number distinctions as well as agreement can be detected relatively early—at least in English—comprehension/production of agreement encoded as a bound morpheme takes a long time to acquire. At present, the reasons for such a lag are unclear. One factor may be the methodology used in the comprehension/production studies, an issue we will discuss in more detail later on. Other factors may be grounded in the properties of the languages tested so far and/or the input received by the children. For example, the fact that one number category is null in these languages (i.e., plural in English, singular in Spanish) may have caused children to focus their attention onto the overt one. Acquisition may also have been influenced by adults' disproportionate use of singular verbal forms around young children.

There is another reason why comprehension might be delayed in English and Spanish. In both languages, overt verbal agreement is marked by a single consonant in (word-final) coda position. Numerous studies on word recognition have found evidence that perception of consonants is affected by their position in a syllable and in a word, both in adults (e.g., Redford & Diehl, 1999) and infants (e.g., Swingley, 2003; Zamuner, 2006; though see Nazzi & Bertoncini, 2009; Swingley, 2009, for positive evidence of coda consonant processing). Swingley (2009) characterizes some of the challenge as follows: ''Word-final consonants are, in general, less clearly articulated; they are heard only after perception of the initial parts of the word has led children to consider an interpretation; and they enjoy less of the benefit of membership in dense phonological neighborhoods.'' Thus, if agreement marking occurred in (word-initial) syllable onset position, earlier comprehension may be found.

French has a subparadigm of agreement of this very sort. While 10% of French verbs have retained phonological encoding of person–number distinctions on the verb itself, the remaining 90% (known as conjugation class I, ending in *–er* in the infinitive) have lost it despite its retention in the spelling. This results in near-complete homophony of the verb form, e.g., /dãs/ ''I, you, he, she, they dance'' (with the exception of first-person plural ''we'' form in *–ons* /dãsõ/ and second-person plural ''you'' form in *–ez* /dãse/, which are extremely rare in child-directed speech). In connected speech, these homophonous verbal forms can be distinguished via subject pronouns under certain conditions. Whenever the verb is consonant-initial the pronunciation of the third-person singular pronoun *il* ''he'' versus plural pronoun *ils* ''they'' is identical, for example, *Il(s) danse(nt)* /i(l)dãs/ ''he/they dance'' though speakers idiosyncratically vary in realizing /l/, independently of number. /i(l)/ thus behaves as a default form in French.

However, for vowel-initial verbs in this conjugation class (e.g., *embrasser* ''to kiss''), which represent about one fourth of the verbs of this class (702 out of 2,673 verbs or 26.3% according to the Manulex ''child'' database, Lété, Sprenger-Charolles, & Colé, 2004; 1,062 out of 4,655 verbs or 22.8% according to the Lexique ''adult'' database, New, Pallier, Ferrand, & Matos, 2001), the phonological fusion of the subject pronoun with the verb results in distinct phonological forms in the third-person singular versus plural. For example, singular *Il embrasse* ''he kisses'' is pronounced /ilãbras/. Its plural counterpart, *Ils embrassent* ''they kiss,'' has two minimally different pronunciations of the pronoun that idiosyncratically vary across speakers: /i**z**ãbras/ and /il**z**ãbras/. In either case, plural marking involves a *liaison* ''linking'' or latent consonant surfacing only with vowel-initial verbs in the immediate presence of a subject pronoun, plus resyllabification whereby the plural marker /z/ finds itself in *onset position of the second syllable*, e.g., /i(**l**).**z**ã.bras/ (Encrevé, 1988; Tranel, 1996). This and other special properties have led a growing number of linguists to propose that French subject pronouns are in fact best analyzed as mere agreement markers (Auger, 1994; Culbertson & Legendre, 2008; Fonseca-Greber & Waugh, 2003; Jakubowicz & Rigaut, 1997; Lambrecht, 1981; Miller, 1992; Pierce, 1992).

The present study, therefore, tests the hypothesis that this French subject–verb agreement subsystem will be comprehended earlier than the English and Spanish type, possibly as early as 24 months of age. In Experiment 1, we built on growing evidence that the intermodal preferential looking paradigm (IPLP; Golinkoff, Hirsh-Pasek, Cauley, & Gordon, 1987; Hirsh-Pasek & Golinkoff, 1996) is an established method for investigating early comprehension of syntax (e.g., Dittmar, Abbot-Smith, Lieven, & Tomasello, 2008; Fisher, 2002; Lidz, Waxman, & Freedman, 2003; Naigles, 1990). In Experiment 2, we exploited recent successful attempts at incorporating pointing as a way of engaging young children (Bernal et al., 2007; Brandone, Pence, Golinkoff, & Hirsh-Pasek, 2007; Dittmar et al., 2008; Maguire, Hirsh-Pasek, Golinkoff, & Brandone, 2008). In both experiments, we followed Soderstrom et al. (2007) by only presenting our subjects with verbs known to them, based on parental report. We expected familiarity to facilitate comprehension.

Specifically, we asked whether young French-learning children from two age groups (24 and 30 months) are able to map an auditory stimulus consisting of singular or plural combinations of a subject pronoun + familiar transitive verb + nonce object noun (e.g. *Il embrasse le taque* ''he kisses the tak'') with visually displayed dynamic scenes involving one or two actors.

The present study also investigates whether frequency might play an additional role, as suggested in Childers et al. (2001). While the target type of subject–verb agreement is found only when the subject pronoun *immediately* precedes the verb its actual manifestation in the adult input is unknown. Large samples of French adult input were analyzed in Experiment 3 with the goal of formulating possible implications of our experimental results for current theories of syntactic acquisition.

Experiment 1

In Experiment 1, we tested comprehension of subject–verb agreement by investigating the ability of 24- and 30-month-old children to match an orally presented utterance to the appropriate video among a pair of actions presented simultaneously. The speech stimuli instantiated a common pattern of subject–verb number agreement in French, that is, a lack of phonological singular–plural distinction on the verb itself but a marking through liaison between the subject pronoun and the vowel-initial verb, resulting in number agreement being expressed as a single consonant in syllable onset position. The task used was the IPLP because it places relatively few demands on children by measuring comprehension through looking time, thus without requiring them to either make meta-linguistic judgments or even perform an action such as pointing, which requires more complex decisional and motor planning.

Method

Participants

Participants included 20 monolingual French-speaking 24-month-olds (10 males, 10 females; M = 23 months, 28 days; range = 22 months, 18 days to 26 months, 3 days), and 20 monolingual French-speaking 30-month-olds (10 males, 10 females;

M = 30 months, 27 days; range = 28 months, 19 days to 35 months, 14 days). An additional seven 24-month-olds were tested but excluded from the experiment, due to fewer than four analyzable trials (1), excessive side bias (> 85% looking to one side; 4), not contributing data to all conditions (1), and video file problem (1). An additional seven 30-month-olds were tested but excluded from the experiment, due to fussiness (2), excessive side bias (2), or for not contributing data to all conditions (3). Children were all tested in Paris. They were recruited from a database of parents who volunteered to participate in child development studies and came from diverse socioeconomic backgrounds.

Materials

Video stimuli Two 8-year-old boys recruited for this purpose were filmed performing 1 of 10 simple actions on unfamiliar objects for which the French children tested did not have a name. For each action, either one boy performed the action alone while the other boy was standing immobile next to the first boy (singular video), or the two boys performed the action together and simultaneously (plural video). Figure 1 shows characteristic still images from the actual videos used for the kissing action. For each action, different unfamiliar objects were used in the singular and plural conditions (a total of 20 unfamiliar objects were used). Thus, the same action was performed on different objects by the single boy (singular video) versus the two boys (plural video). All video sequences lasted 6 s.

Audio stimuli. All speech stimuli were recorded by the same female speaker using moderate child-directed speech. Ten verbs, referring to the ten actions of the videos, were used: *accrocher* "to hook," *allumer* "to switch on," *apporter* "to bring," *arrêter* "to stop," *attacher* "to tie," *attraper* "to catch," *embrasser* "to kiss," *enlever* "to remove," *essuyer* "to wipe," and *ouvrir* "to open." These verbs were chosen because they fulfill several important constraints. They are transitive and belong to the dominant conjugation class (Class I), except for *ouvrir* "to open," which nevertheless follows the same phonological pattern; third-person singular and plural forms of the verb are homophonous. They have been found to be known by many children in previously collected MacArthur Communicative Development Inventory (MCDI) data (Kern, 2003; Nazzi, 2005; Nazzi, Floccia, Moquet, & Butler, 2009; Nazzi & Pilardeau, 2007) and in a large cross-sectional corpus (Le Normand, 1986). All verbs are vowel initial, with phonologically identical third-person singular and third-person plural forms, number agreement being only signaled by liaison between the pronoun and the verb. Of the two pronunciations of the plural pronoun (/iz/, /ilz/), the native speaker who recorded the stimuli consistently used the former.

The verbs were embedded in short sentences consisting of the third-person subject pronoun in either singular (*il* "he") or plural (*ils* "they") form, the verb, and an NP (determiner *le* "the" + noun). Pseudo-words rather than real nouns were used as direct objects of the transitive verbs to refer to the unfamiliar objects. We used 20 different pseudo-words (one for each of the unfamiliar objects), which all had a consonant–vowel–consonant structure (e.g., /gef/). The decision to use unfamiliar objects and pseudo-words was made on several grounds, including neutralizing possible lexical noun knowledge effects across subjects, eliminating possible effects of the predictability of the object reported in imitation tasks (Valian, Prasada, & Scarpa, 2006), as well as a possible but problematic distributive interpretation associated with singular phrases/sentences. A sentence like *Il embrasse la poupée* "He is kissing the doll" matches both a scene in which only one boy kisses the doll and a scene in which two separate boys are kissing the doll (see Kouider et al., 2006, for a similar argument). In contrast, the use of distinct pseudo-nouns as objects (e.g., *embrasser le voube* "to kiss the voub" vs.

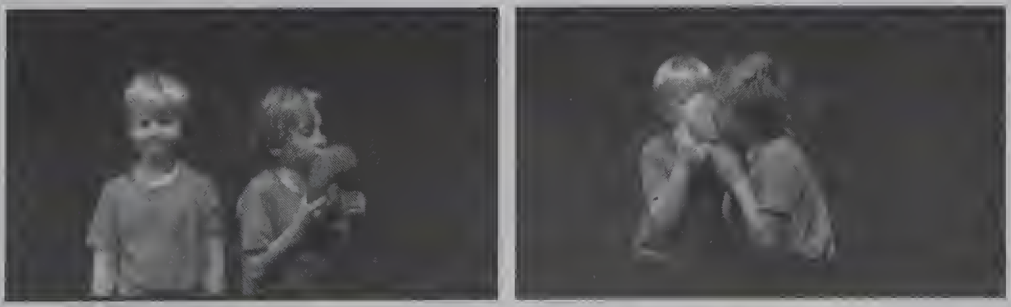

Figure 1. Video stimuli in the singular (left screen) and plural (right screen) conditions.

embrasser le taque "to kiss the tak") refer to events that are distinguished on the basis of the unfamiliar objects involved. A proficient user of French would need to make use of their knowledge of *il* (singular) versus *ils* (plural) to assign a singular or plural interpretation to *il embrasse le voube* and *ils embrassent le taque*.

Procedure

Prior to coming to the lab, parents were asked to name which of the ten verbs used in the experiment their child knew. They were not asked whether their child knew specific forms of the verbs. Right before their visit, parents also completed a French version of the MCDI questionnaire (Fenson et al., 1993; Kern, 2003) modified by the authors to include more verbs and to break down pronominal forms into subcategories to allow for correlation analyses (see below). The MCDI is a parent-friendly, successful, and reliable tool for measuring lexical and function words a young child understands and/or produces spontaneously. MCDI questionnaires were returned for 18 (of 20) 24-month-olds and 17 (of 20) 30-month-olds.

Each child was tested individually in a soundproof booth for about 10 min using the IPLP. Children sat on a parent's lap during the whole session. The parent, wearing dark glasses rendered completely opaque by covering the inside of the lenses with thick paper, was blind to the video stimuli. Each child was presented with 6–8 trials (depending on the number of test verbs reported to be known by their parent). All trials consisted of the sequence of events described in the following paragraph.

The child's attention was first centered by flashing a central light located between the two presentation screens (the child facing the whole display). Once the child looked at the central light, the baseline phase started, in which two videos were simultaneously displayed on two screens in silence for 6 s. Both videos depicted the same action, one being the singular video and the other being the plural video. After this video presentation, the central light was flashed again. Once the child looked at it, the test phase started, consisting of the audio presentation of a speech stimulus matching one of the two scenes, immediately followed by a 6-s-long presentation of the same two videos presented during the baseline phase. Once the test phase was over, a 3-s eye-catching video (a "dance" performed by the two boys) was displayed on the screen of the matching video to mark the end of the trial (following Kouider et al., 2006). Previous studies have shown that children tend to look longer at the scene matching the speech stimulus during test compared to baseline (e.g., Golinkoff et al., 1987; Naigles, 1990).

For half of the trials, the speech stimulus corresponded to the singular video, while it corresponded to the plural video for the other half of the trials. Moreover, the side of the matching video was counterbalanced within participants. Children who knew only six verbs (instead of eight) were tested on the same number of singular (three) and plural (three) videos. The last two videos of the session (one singular, one plural) were displayed on the same screen.

Coding and Reliability

A digital video camera placed between the two TV screens was used to record the child's looks during the baseline and test phases. The videos were coded offline frame by frame using SuperCoder (Hollich, 2005). For each frame, a trained coder blind to the condition (i.e., whether the audio stimuli were the singular or the plural) coded whether the child was looking at the matching video, at the nonmatching video, or away. Then, for each trial, we calculated the percentage of time that the child spent looking at the matching video compared to the nonmatching video. Trials in which children only looked at one video during baseline were discarded from the analysis. Overall, we analyzed a mean of 5.25 trials (out of a mean of 7.30 trials actually presented) per 24-month-old and a mean of 5.15 trials (out of a mean of 7.45 trials actually presented) per 30-month-old. Ten percent of the data were recoded by a different trained coder, with an average agreement of 98% for the 24-month-olds, and 94% for the 30-month-olds.

Results and Discussion

For both the baseline and test phases, the percentages of looking toward the matching videos were averaged over trials separately for trials in which the singular video versus the plural video was the target, leading to four measures per child.

Mean percentages to the matching videos were entered into a three-way analysis of variance (ANOVA) with the main between-subject factors of age (24 vs. 30 months) and the main within-subject factors of phase (baseline vs. test) and number (singular vs. plural target). The effect of phase approached significance, $F(1, 38) = 3.73$, $p = .061$,

$\eta_p^2 = .09$, indicating that the children tended to look longer at the matching videos during test ($M = 52.27\%$, $SD = 17.36$) than during baseline ($M = 47.01\%$, $SD = 8.80$). However, the triple interaction also approached significance, $F(1, 38) = 3.33$, $p = .076$, $\eta_p^2 = .08$, suggesting that the effect of phase was modulated by age and/or number. No other effect or interaction reached significance.

In order to specify the triple interaction, separate ANOVAs with the two factors of phase and number were conducted for each age group. At 24 months of age (Figure 2), both main effects were nonsignificant (both *F*s < 1). For the phase factor, only ten of the twenty 24-month-olds increased their looking times toward the target video between familiarization and test. However, the Phase × Number interaction was significant, $F(1, 19) = 7.06$, $p = .016$, $\eta_p^2 = .27$. Planned comparisons, though not reaching significance, showed that the 24-month-olds tended to decrease their looking towards the singular video in the singular target trials, $F(1, 19) = 1.29$, $p = .27$, $\eta_p^2 = .06$, while they tended to increase their looking toward the plural video in the plural target trials, $F(1, 19) = 2.96$, $p = .10$, $\eta_p^2 = .14$. Overall, this pattern shows that the 24-month-olds tended to increase their looking toward the plural video between baseline ($M = 46.37\%$, $SD = 11.68$) and test ($M = 54.02\%$, $SD = 25.16$). This was confirmed by an ANOVA with the factors of phase and number on the variable percent looking at plural video showing a main effect of phase, $F(1, 19) = 7.06$, $p = .016$, $\eta_p^2 = .27$, and no other effect or interaction, $F(1, 19) < 1$. Although it is unclear why they did so, this pattern of results brings no evidence in support of an understanding of number agreement at 24 months of age.

At 30 months of age (Figure 3), there was a main effect of phase, $F(1, 19) = 9.09$, $p = .007$, $\eta_p^2 = .32$, establishing that the older children looked longer at the matching video after having heard the speech stimulus ($M = 53.1\%$, $SD = 8.5$) than during baseline ($M = 46.3\%$, $SD = 12.9$). This conclusion is also supported by the fact that fourteen of the twenty 30-month-olds increased their looking times toward the target video between familiarization and test ($p = .058$, binomial test). There was also a main effect of number, $F(1, 19) = 5.77$, $p = .027$, $\eta_p^2 = .23$, indicating that the older children tended to look longer toward the targets in the trials of the singular condition. Importantly though, there was no interaction between the two factors, $F(1, 19) < 1$, indicating that the older children increased their looking times toward the matching video between baseline and test in both the singular and plural conditions. This pattern of results is compatible with an understanding of number agreement at 30 months of age.

The present results reveal that the linguistic stimulus did alter the older children's initial preference. While the 24-month-olds looked longer at the video depicting two boys performing an action in the testing phase, regardless of singular versus plural verbal stimulus, the 30-month-olds systematically looked longer at the matching video in the testing phase both in the singular and plural conditions, compared with the silent phase.

Because the agreement form tested in the present study relies on the contrast between third-person singular (*il*) and plural (*ils*) subject pronouns, we

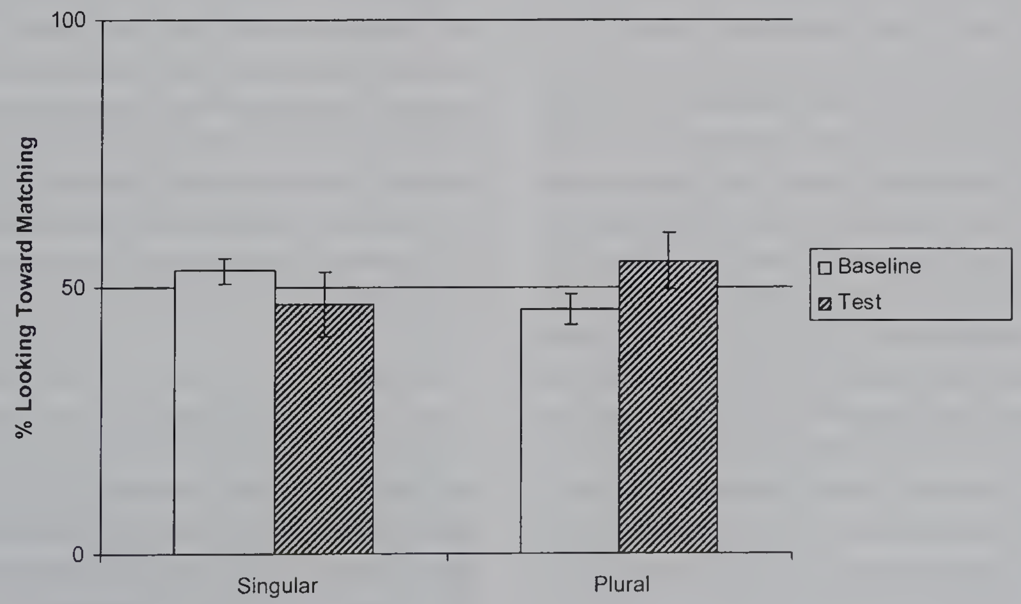

Figure 2. Mean percent looking times (and *SE*s) toward the matching video in silent baseline and at test, broken down by the number of the target, at 24 months of age.

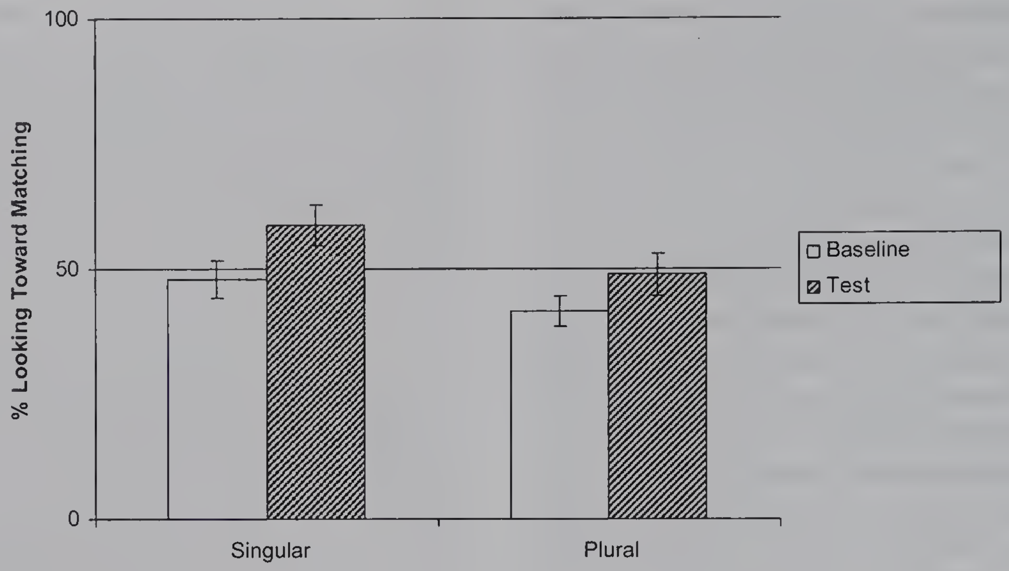

Figure 3. Mean percent looking times (and *SE*s) toward the matching video in silent baseline and at test, broken down by the number of the target, at 30 months of age.

computed children's knowledge of these elements according to parents' responses on the MCDI questionnaires filled out at the time of testing. At 24 months, 50% of the children were reported to understand singular *il* versus 29% for plural *ils*. At 30 months, 96% of the children were reported to understand singular *il* versus 88% for plural *ils*. These numbers show, first, an increase in comprehension of these pronouns between the two ages, for both *il*, $\chi^2(1, N = 35) = 6.32$, $p = .012$, $\phi = .49$, and *ils*, $\chi^2(1, N = 35) = 10.70$, $p = .001$, $\phi = .61$, suggesting that 30-month-olds may have representations of the singular and plural forms they use while 24-month-olds may not. Second, they establish a lack of singular–plural asymmetry, for both 24-month-olds, $\chi^2(1, N = 18) = 1.05$, $p = .31$, $\phi = -.23$, and 30-month-olds, $\chi^2(1, N = 17) = .34$, $p = .55$, $\phi = -.10$, corroborating the lack of an asymmetry in the IPLP results.

Correlation analyses between children's performance in the IPLP task (three variables: overall score, score on singular trials, score on plural trials) and MCDI data (six variables: total number of words/verbs/pronouns understood or produced) were also carried out for both age groups. The only significant correlation was a positive correlation found for 24-month-olds between performance on singular trials and total number of verbs understood, $r(17) = .54$, $p = .02$. No significant correlation was found at 30 months. These results suggest a rather weak link between lexical acquisition and comprehension of agreement, although caution is required in interpreting the present pattern of correlations given the small numbers of participants at each age.

Overall, the results of the present IPLP study demonstrate that 30-month-old children acquiring French are able to distinguish the singular and the plural marking expressed as the linking consonants /l/ versus /z/ in onset position of the second syllable of otherwise phonologically identical verbs. In particular, they were able to match these forms to the target stimuli, in the absence of any additional morphosyntactic or lexical cues. No such evidence could be found for 24-month-olds. These results, therefore, provide evidence for comprehension of a single number contrast by 30 months, which is probably emerging somewhere between 24 and 30 months of age. Like in Kouider et al. (2006) and Wood et al. (2009), young children showed comprehension of *verbal* number marking but there were significant differences in the stimuli. In the English case, the verbal contrast was lexical (*is* vs. *are*) and 24-month-olds showed comprehension with familiar or nonce objects only when several number cues were presented (e.g., "Look, there **are some** blickets" vs. "Look, there **is a** blicket"). When a single nominal cue in the form of the bound morpheme -*s* was presented, children younger than 36 months did not show comprehension.

Because the results of the French IPLP experiment clearly challenge the conclusion based on English and Spanish that subject–verb agreement is mastered late, around age 5 (Johnson et al., 2005; Pérez-Leroux, 2005), we set out to replicate them, using a different experimental technique. In Experiment 2, we administered a pointing task to a separate group of 30-month-olds and asked whether the 6.8% increase in looking time observed between baseline and test in IPLP revealed an understanding of number agreement stable enough to be able to guide a pointing response, a task requiring both decisional and motor planning.

Experiment 2

IPLP has been widely and successfully used to investigate other aspects of language acquisition, in particular, argument structure in younger children (Hirsh-Pasek, Golinkoff, & Naigles, 1996; Naigles, 1990, 1996; Naigles & Bavin, 2002) because it places very few demands on them. For the present agreement study, it is worth asking whether adding some burden on children would result or not in comprehension failure. This, in turn, would reveal how robust the underlying representation of subject–verb agreement is, say, at 30 months of age. Therefore, Experiment 1 was replicated for 30-month-olds using a pointing task (more similar than IPLP to the methods used in previous studies on subject–verb agreement). If their representation of subject–verb agreement is stable, pointing is likely not to hinder comprehension, especially since children in that age range are known to succeed in this task (Brandone et al., 2007; Dittmar et al., 2008; Maguire et al., 2008).

Method

Participants

Participants included 16 monolingual French-speaking 30-month-olds (8 males, 8 females; *M* = 30 months, 12 days; range = 28 months, 18 days to 32 months, 11 days). Six additional children were tested but excluded from the experiment due to their refusing to participate (1) or pointing in fewer than four trials (5). Children were all tested in Paris. They were recruited from a database of parents who volunteered to participate in child development studies and came from diverse socioeconomic backgrounds.

Materials

We used the same visual and verbal stimuli as in Experiment 1 (of the two pronunciations of the plural pronoun, /iz/ and /ilz/, the experimenter consistently used the latter). Children were only presented with verbs that they comprehended according to parental report.

Procedure

Prior to coming to the lab, parents were asked to name which of the 10 verbs used in the experiment their child knew. Right before their visit, parents also completed a French version of the MCDI modified by the authors for present purposes. MCDI questionnaires were returned for 12 (of 16) children.

Each child was tested individually in a soundproof booth for about 10 min using a pointing task. Children sat on a parent's lap during the whole session. The parent, wearing dark glasses rendered opaque by covering the inside of the lenses, was blind to the video stimuli. The (female) experimenter sat to the immediate right of, and slightly behind, the child. Having the experimenter sit fully behind the child was tested but proved problematic: The child would frequently turn back because of interest or to seek approval. When pronouncing the target utterance, the experimenter was careful not to look at the child or the screens; rather she stared at the central light between the two screens so as not to influence the child's pointing.

The session started with up to four training trials intended to set up the pointing game. The structure of the trials was similar to that in Experiment 1, and it was the same for the training and test trials. The child's attention was first centered by flashing a central light located between the two presentation screens (the child facing the whole display). Once the child looked at the central light, a pair of pictures of bright, easily recognizable objects was shown in silence for 6 s. Then the screens turned black and the experimenter named one of the two objects and asked the child to point to it (e.g., *Tu as vu la pomme? Montre-moi avec ton doigt où elle se trouve la pomme, montre-moi la pomme* "Did you see the apple? Show me with your finger where the apple is, show me the apple"). The two images immediately reappeared on their respective screens for 6 s. The child's task was to point to the matching screen. If the child didn't point during the first seconds, the experimenter repeated the invitation once to give the child another chance at responding and then, regardless of response, moved onto the next trial. Each trial ended with the 3-s eye-catching video displayed on the matching screen, as done in Experiment 1, following Kouider et al. (2006).

Each child was then presented with eight trials of familiar verbs (all knew at least eight of the verbs used in the present experiment). They were simultaneously presented the 6-s singular/plural versions of the actions used in Experiment 2 twice, first in silence then following the experimenter's request (e.g., *Tu as vu? Ils attrapent le zappe, montre-moi avec ton doigt où ils attrapent le zappe, montre moi où ils attrapent le zappe* "Did you see? They are catching the zap, show me with your finger where they are catching the zap, show me where they are catching the zap").

For each child, the target was the singular action four times and the plural action the other four times (in random order). The order of presentation of the different actions/verbs was randomized by the experimenter, and the side of the matching video was counterbalanced within participants for each condition (singular/plural).

Coding and Reliability

Coding of children' pointing was done online by the experimenter, but the sessions were videotaped using a digital video camera placed between the two screens. Each trial was coded as correct (score = 1) or incorrect (score = 0). A response was coded as correct only if the child clearly and decisively pointed to one screen. Any hesitant, double pointing or refusal to point resulted in the elimination of the corresponding trials. Overall, children clearly pointed on 7.25 of 8 trials. The data were first coded online, then entirely recoded offline by an assistant not familiar with the study and blind to the conditions of each trial. Interrater reliability was of 96%. Only five trials led to different answers by the two coders; these trials were viewed again by the two original coders and a third coder, and coding agreement was easily reached.

Results and Discussion

There was no significant difference between the singular and plural conditions, $t(15) = .48$, $p = .64$, two-tailed, $d = .17$ (Figure 4). Overall, children pointed at the matching video 61.93% ($SD = 14.16$) of the time ($M = 64.06\%$, $SD = 26.48$ for singular; $M = 59.90\%$, $SD = 23.02$ for plural, the slightly better performance for singular being entirely due to 1 child who only pointed to singular actions), which is significantly above the 50% chance level, $t(15) = 3.37$; $p = .004$, two-tailed, $d = 1.74$. There was a majority of 12 children who gave more correct points versus 2 children who gave fewer correct points and 2 children who gave as many correct and incorrect points, $\chi^2(2, N = 16) = 10.38$, $p = .006$, $\phi = .38$.

Just as in Experiment 1, the lack of singular versus plural asymmetry revealed in the pointing task results is corroborated by MCDI evidence that 30-month-olds have the same level of comprehension of singular *il* and plural *ils*: Ninety percent of the 30-month-olds in Experiment 2 (compared to 96% in Experiment 1) were reported to understand *il* versus 80% for *ils* (compared with 88% in Experiment 1). Note that both groups of 30-month-olds are clearly at the same level of acquisition of these third-person subject pronouns, both for *il*, $\chi^2(1, N = 27) = .16$, $p = .69$, $\phi = -.08$, and *ils*, $\chi^2(1, N = 27) = .34$, $p = .56$, $\phi = -.11$.

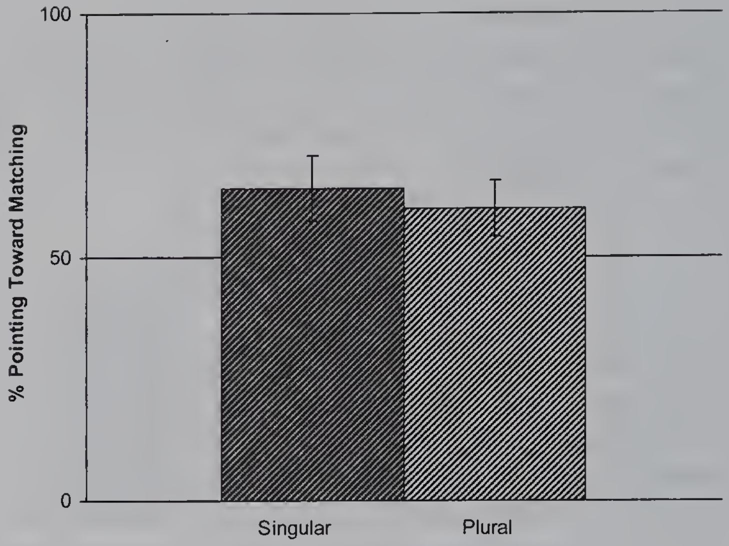

Figure 4. Mean percent pointing (and *SE*s) toward the matching video at test, broken down by the number of the target, at 30 months of age.

As in Experiment 1, we also performed correlation analyses between children's performance (three variables: overall score, score on singular trials, score on plural trials) and MCDI data (six variables: total number of words/verbs/pronouns understood or produced). There was a significant positive correlation between overall performance and total number of verbs understood, $r(11) = .59$, $p = .04$, and a marginal positive correlation between performance on singular trials and total number of verbs understood, $r(11) = .55$, $p = .06$. Again, these results suggest a rather weak link between lexical acquisition and comprehension of agreement, although caution is required in interpreting the present data given the small numbers of participants.

Overall, Experiment 2 shows that increasing the decisional and motor burden on 30-month-olds does not hinder children's performance. Thirty-month-old children were able to distinguish between third-person singular and plural and match the plural and singular expressions of liaison to the target visual stimuli. Moreover, no asymmetry between children's performance in the singular versus plural conditions was revealed by the analyses. Representations of subject–verb agreement for the forms tested, thus, appear to be rather stable at 30 months of age.

The results of Experiments 1 and 2 raise the issue of whether children's performance is closely or loosely tied to properties of the adult input. Recall that Childers et al. (2001) suggested that Spanish-learning children's preference for singular agreement forms in a pointing task was paralleled by a singular bias in the adult input, albeit in different varieties of Spanish. Does a similar pattern extend to French or not? The experimental results in Experiment 1 and 2 show no singular–plural asymmetry. Is such an asymmetry also absent in French adult input? We analyzed large samples in Experiment 3 to determine the frequencies of singular and plural bare pronoun + verb combinations similar to those used in our stimuli and tested the hypothesis put forward by Childers et al. (2001).

Experiment 3

We analyzed the occurrence in child-directed speech and in spontaneous child production of the type of third-person subject pronoun + verb combinations we used in our experimental stimuli.

Method

For our analysis of the frequency of use of the third-person singular and plural subject pronouns in adult input, we used the Child Language Data Exchange System (MacWhinney, 2000) data of spontaneous speech by native French mothers of 5 monolingual, normally developing children acquiring (Parisian) French for a total of more than 54,000 utterances: dizygotic twins Camille and Pierre, ages 15–25 months and 16–27 months, respectively (Hunkeler, 2005); Pauline, age 14–30 months (Bassano & Mendes-Maillochon, 1994); Anne, age 22–30 months (Plunkett, 2002); and Grégoire, age 21–29 months (Champaud corpus).

We coded all occurrences (full and reduced) of the third-person singular pronoun *il* (/il/ or /i/) and third-person plural pronoun *ils* (/il/, /ilz/, /iz/) in the absence of a full NP subject, distinguishing eight types of verb forms, depending on: (a) number (singular or plural), (b) whether the verb starts with a vowel or a consonant (which determines the actual pronunciation of the pronoun), and (c) whether the verb has a regular ending or form (Class I) or irregular (other classes).

If the verb is regular and starts with a vowel (Type A), marking of number is carried by the preverbal pronoun only (*Il embrasse* /ilãbras/ "He kisses" vs. *Ils embrassent* /i(l)zãbras/ "They kiss"). This is the combination type used in Experiments 1 and 2. Three other types are found in French. If the verb is regular and starts with a consonant (Type B) number distinctions are all silent; the default form /i(l)/ is used (e.g., *Il(s) danse(nt)* /i(l)dãs/ "He or they dance"). If the verb is irregular and starts with a vowel (Type C), number is redundantly marked by the pronoun and the verb root or ending (e.g., *Il a* /ila/ "He has" vs. *Ils ont* /i(l)zõ/ "They have"). If the verb is irregular and starts with a consonant (Type D), marking of number is carried by the ending or root only, the distinction between *il* and *ils* being silent again (e.g., *Il prend* /i(l)prã/ "He takes" vs. *Ils prennent* /i(l)prɛn/ "They take").

Results and Discussion

The results are displayed in Table 1 with some specific points of comparison of the adult input with the stimuli used in Experiments 1 and 2.

The percentage of child-directed utterances containing any bare third-person pronoun + verb combination out of the total number of child-directed utterances varies across children (from 4% to 18%) but it remains overall quite low. The percentage of singular combinations out of all third-person pronoun + verb combinations is always higher than plural combinations, ranging from 62% for Pierre to 92% for Grégoire and disproportionally so for four of five children. Overall, this means that French-learning children are not systematically exposed to a large proportion of third-person pronoun + verb combinations compared to other types of utterances (e.g., noun + verb, first- or second-person subject pronoun + verb). Nor are they systematically exposed to any morphophonological contrast between third-person singular and plural pronoun + verb combinations, regardless of verbal type given the marked asymmetry in favor of singular forms.

Type A forms (in bold) are similar to the forms used in our comprehension stimuli. As shown in Table 1, Type A forms are relatively rare in the adult input (except for Camille, 39%) compared to other types of verb forms, both in the singular (2%–8%, out of all singular combinations) and in the plural (0%–12%, out of all plural combinations).

A parallel analysis of spontaneous child production in the same corpora is displayed in Table 2. Up to 30 months of age, children vary in their overall level of spontaneous production of bare third-person pronoun + verb combinations. Yet

Table 1
Frequency of Adult Third-Person Pronoun + Verb Combinations in Adult Input (Type A = Combinations Used in Experimental Stimuli)

Corpus and age in months	Camille (15–25)	Pierre (16–27)	Pauline (14–30)	Anne (22–30)	Grégoire (21–29)
Total adult utterances	1,875	1,558	8,873	35,480	6,430
Total singular and plural combinations, Types A–D (out of all adult utterances)	8% (151/1,875)	18% (279/1,558)	5% (421/8,873)	4% (1,374/35,480)	10% (639/6,430)
Singular combinations, Types A–D (out of all combinations)	91% (137/151)	62% (174/279)	90% (381/421)	82% (1,130/1,374)	92% (589/639)
Singular combinations, Type A (out of all singular combinations)	39% (53/137)	2% (3/174)	8% (30/381)	7% (79/1,130)	8% (45/589)

Table 2
Frequency of Spontaneous Child Third-Person Pronoun + Verb Combinations (Type A = Combinations Used in Experimental Stimuli)

Corpus and age in months	Camille (15–25)	Pierre (16–27)	Pauline (14–30)	Anne (22–30)	Grégoire (21–29)
Total child utterances	1,334	1,057	3,943	5,468	4,037
Total singular and plural combinations, Types A–D (out of all adult utterances)	0% (0/1,334)	0% (0/1,057)	1% (46/3,943)	3% (150/5,468)	3% (133/4,037)
Singular combinations, Types A–D (out of all combinations)	0% (0/0)	0% (0/0)	89% (41/46)	83% (125/150)	94% (125/133)
Singular combinations, Type A (out of all singular combinations)	0% (0/0)	0% (0/0)	0% (0/41)	2% (3/125)	3% (4/125)
Plural combinations, Type A (out of all plural combinations)	0% (0/0)	0% (0/0)	0% (0/5)	0% (0/25)	0% (0/8)

they are systematically found to produce more singular than plural forms if they produce any (ranging from 83% to 94%), and very few vowel-initial verbs.

In sum, the analysis of five corpora provides a clear picture of the particular verbal forms of the language French-learning children are generally exposed to. First, they are exposed to a much higher proportion of singular than plural third-person pronoun + verb combinations across all types of morphophonological instantiations. Second, vowel-initial verbs varying in the singular versus plural because of liaison constitute an infrequent morphophonological subclass in the adult input. Therefore, French-learning children are rarely exposed to the type of stimuli we used in comprehension Experiments 1 and 2, a situation different from the relatively frequent subject–verb agreement forms studied in Spanish, and to a lesser extent, English. Moreover, like its Spanish counterpart, the French adult input displays a singular bias; however, such a bias was not reflected in our comprehension results, contrary to the singular bias found in Spanish by Childers et al. (2001).

General Discussion

The main finding of the present study is that French-learning 30-month-olds distinguish singular versus plural subject–verb agreement forms signaled in the plural by a /z/ sound at the onset of the second syllable of a simple verbal utterance and use them to guide looking or pointing to events with singular or plural agents. While 24-month-olds did not succeed at the preferential looking task, 30-month-olds were able to match the same visual scene with a corresponding verbal stimulus in two different experimental tasks, with and without added decisional and motor planning with no incidence on the results (the often reported increased sensitivity of looking over pointing tasks is thus not found in our study). This suggests that 30-month-olds have knowledge of subject–verb agreement, and that this knowledge is independent of the demands of the task and therefore robust.

While early sensitivity to number agreement cues may be present in English-learning children as young as 16 months (Soderstrom et al., 2007) and comprehension of singular–plural morphology has been found in 24-month-olds provided it is lexicalized and occurs in combination with nominal cues (Kouider et al., 2006; Wood et al., 2009), comprehension of bound singular–plural morphology had not been found before the age of 3 or 5, depending on the study (Childers et al., 2001; cf. Johnson et al., 2005; Pérez-Leroux, 2005). To the best of our knowledge the results of Experiments 1 and 2 are the first to date that point to an earlier age—30 months—for comprehension of bound number morphology in the verbal domain in the absence of any additional cue.

Why do we find such a difference in age of comprehension of subject–verb agreement in French versus English and Spanish? Our main hypothesis relates it to the different encoding of number in the languages investigated: suffixal in English and Spanish versus "prefixal" in French. In some speech perception and word recognition/learning tasks, children have been shown to process consonants better in onset position than in coda position (Swingley, 2003; Zamuner, 2006; though see Nazzi & Bertoncini, 2009; Swingley, 2009, for findings failing to find an onset/coda asymmetry). Accordingly, if the /z/ consonant that marks plural agreement in French through the phenomenon of liaison was treated as an onset consonant (a likely possibility that will have to be directly investigated in the future), it might explain why we found better/earlier processing than for the –/s/ and –/n/ coda consonants marking agreement in English and Spanish, respectively. It is as if agreement marking earlier in the word entails that it is heard precisely at the time children are considering an interpretation of the verb (as onset consonants seem to have more influence on processing in early word recognition tasks; Swingley, 2003).

This difference in encoding may not, however, explain the size of the age gap (30 months/2 years and 6 months vs. 5 years of age). Potentially crucial procedural differences, in particular in the nature and quality of the stimuli used, may also have contributed to the results. In both the English and Spanish studies conducted by Johnson et al. (2005) and Pérez-Leroux (2005), children looked at static pictures of, say, one duck versus two ducks swimming. The pictorial representation of the action was necessarily abstract, with only a wavy line depicting water, and no representation of swimming per se. This may have resulted in insufficient salience of the verb causing subjects to focus on the subject for number information that was by design masked by using *s*-initial verbs (the stimuli used in Childers et al. (2001) appear to have been similar but full details of illustration are lacking). Using dynamic videos in the French study with actual children performing various actions may have had a facilitating effect.

However, it is also possible that the use of high-quality images rather than simplified, abstract pictures, and not the dynamic dimension of our stimuli per se, helped the 30-month-olds in our study. It could even be that the dynamic actions added some processing weight, as the discriminating elements between the singular and plural versions of the actions were only observable during a limited portion of the video. Then maybe the failure of the 24-month-olds is not due to the lack of abstract representations of subject–verb agreement but rather to difficulties at coprocessing the complex visually dynamic stimuli and the verbal stimulus within 6 s. If so, using high quality images extracted from actual videos, such as a representative frame of the singular and plural conditions, may achieve the goal of providing simpler stimuli while retaining the saliency of the action denoted by the verb and help 24-month-olds show comprehension of subject–verb agreement. On the contrary, should 24-month-olds fail to show comprehension under such conditions, then we would be closer to concluding that abstract representations of subject–verb agreement emerge somewhere between 24 and 30 months of age. In light of the results obtained by Kouider et al. (2006) and Wood et al. (2009), this would suggest that comprehension failure in 24-month-olds is tied instead to the nonredundant and nonlexical marking of number agreement contrasts in French.

The present findings have two implications for the acquisition of subject–verb agreement. First, comparing her Spanish results with English results by Johnson et al. (2005), Pérez-Leroux (2005) concluded that children show a preference for the number category that is instantiated by overt morphology, namely, singular *–s* in English and plural *–n* in Spanish. This conclusion is challenged by our results. Children failed to show better performance on plural verbal forms than singular ones despite the fact that plural agreement is always signaled by /z/ with vowel-initial verbs in French. Second, Childers et al. (2001) attributed their finding that young Spanish-learning children show a significant preference for third-person singular verbal forms over plural forms to a disproportionate number of singular forms in the adult Spanish input. This interpretation is not supported by our results, as the French-learning children we tested did not display an overall preference for singular verbal forms, despite a singular bias in the adult input.

Our findings also bear on previous claims concerning the acquisition of liaison in French because the plural number agreement tested is phonologically realized through liaison. In a picture description task requiring children to produce pronoun + vowel-initial verb combinations like *Ils écrivent* "They write" after the prompt *Ici les garçons lisent et là?* "Here the boys read and there?" Gallot, Spinelli, and Chevrot (2008) showed that 31- to 46-month-olds produce correct, obligatory liaison only 68% of the time. Experiments 1 and 2 provide evidence for awareness of liaison in verbal contexts by 30 months, an age when children's production of liaison is not yet systematic. A possible explanation for this discrepancy relates to Gallot et al. (2008)'s use of a picture description task requiring children to cooperate and remember a prompt. This explanation is indirectly supported by independent studies having revealed a gap between production of *–s* marking in English in the context of a sentence completion with nonce verbs task (Berko, 1958) versus spontaneous production (Brown, 1973).

Our study also contributes to the growing literature on the role played by function words in acquiring language. Previous studies established that subject pronouns like *il* facilitate early segmentation of verbs and comprehension of verbs as denoting actions. Regarding segmentation, Marquis and Shi (2008) tested French-learning 11-month-olds on novel verb segmentation on passages containing two combinations of subject noun + verb and five combinations of a subject pronoun + verb, and found that these children at the onset of vocabulary learning were able to segment monosyllabic verbs out of two-word sequences. Regarding comprehension, Bernal et al. (2007), using a pointing task, taught novel verbs to 23-month-old French children watching a moving object within sentences consisting of the subject pronoun *il* + verb (e.g., *Il poune par là* "It's pooning there") and novel nouns to a control group (e.g., *Un poune est là* "A poone is here") with the same visual stimuli. These children were able to distinguish verb/actions from noun/objects on the basis of their syntactic environment, the pronoun *il* versus the determiner *un*. Our study adds to this body of research on function words by establishing that by 30 months of age, children comprehend number subject–verb agreement based on pronoun-related phonological form variations.

Finally, our study has implications for general theories of syntactic acquisition. One of the main current debates in first language acquisition focuses on whether early acquisition proceeds via item-based schemas closely tied to input frequency (e.g., Lieven, Pine, & Baldwin, 1997; Theakston & Lieven, 2005; Tomasello, 2000) or abstract representations largely independent of input frequency (e.g., Chomsky, 1981; Fisher, 2002; Lidz & Gleitman, 2004). Overall, the results of the present experimental studies combined with the corpus study challenge attempts at establishing a close connection between child performance and adult input, as children were clearly sensitive to both singular and plural agreement relations at an early age despite a pattern of infrequent and singular-dominant use of these forms by adults.

Although constructivist accounts do not make precise claims about the amount of input required for item-based learning of singular–plural marking, our results nevertheless indicate that very little input is needed to master the liaison-based subject–verb agreement system of French. Accordingly, we interpret our data as evidence that 30-month-old French-learning children have reached a milestone in the acquisition of subject–verb agreement in that they have acquired the abstract categories of singular/plural instantiated by a single cue, a third-person singular/plural pronoun triggering liaison, as well as the contrast between singular and plural. Their linguistic representations of number are abstract in kind rather than item-based, as well as robust. In a follow-up study, we plan to test whether these representations are robust enough to support comprehension in noun/verb variants of Experiments 1 and 2 in 30-month-olds.

To end on this issue, because language acquisition is not possible without linguistic input, the present results raise the question of how 30-month-olds have learned subject–verb agreement given the low frequency of the relevant forms in the adult input. We suspect that it is the cumulative effect of acquiring the entire system of subject–verb agreement in French that makes it possible to learn all its expressions, ranging from the morphological marking of number on the subject NP, doubling by a pronoun, the verb itself if irregular, as well as liaison where appropriate. A particularity of spoken French including child-directed French (Culbertson & Legendre, 2008) may be relevant. Spoken French favors pronoun doubling or the co-occurrence of a subject NP and a pronoun agreeing in person and number (e.g., *Jean il est parti* "John he left"; *Marie elle est partie* "Mary she left"). Depending on whether the verb itself displays regular or irregular person/number marking, whether the verb is vowel or consonant initial, and whether the subject NP includes a determiner or not, a nonadjacent dependency results that may include up to four cues: ***L'animal il a*** *une trompe* "The animal it has a trunk" versus ***Les animaux ils ont*** *une trompe* "The animals they have a trunk." The redundancy in morphophonological cues of number including two identically sounding liaisons marking plural (*Les animaux* /le**z**animo/; *ils ont* /i(l)**z**õ/) may well be salient enough for abstract representations to follow and for the use of a single cue with low saliency in the interpretation of third-person singular versus plural subjects by 30-month-old children.

Reading Minds: The Relation Between Children's Mental State Knowledge and Their Metaknowledge About Reading

Serena Lecce, Silvia Zocchi,
Adriano Pagnin,
and Paola Palladino
University of Pavia, Italy

Mele Taumoepeau
University of Otago, New Zealand

The relation between children's mental state knowledge and metaknowledge about reading was examined in 2 studies. In Study 1, 196 children (mean age = 9 years) were tested for verbal ability (VA), metaknowledge about reading, and mental state words in a story task. In Study 2, the results of Study 1 were extended by using a cross-lagged design and by investigating older children (N = 71, mean ages = 10 years at Time 1 and 11 years at Time 2) for mental state knowledge, metaknowledge about reading, and VA. Results showed a significant relation between early cognitive (but not emotion) mental state knowledge and later metaknowledge about reading, controlling for VA. Results suggest close links between different aspects of children's knowledge about the mind.

Children's knowledge about the mind represents one of the most productive areas of research in child development. Extensive research has documented the developmental trajectory of preschool children's theory of mind (ToM) or the ability to attribute mental states to themselves and others. A well-established development in children's ability to explain, predict, and influence others' behaviors is the understanding that people may act on the basis of false beliefs (Premack & Woodruff, 1978; Wellman, Cross, & Watson, 2001). Despite this wealth of research, less is known about the consequences of children's earlier knowledge about mental states as it relates to aspects of older children's mind understanding such as metacognitive ability, that is, the ability to reflect on cognitive activity that takes itself as the cognitive object or that regulates any aspect of cognitive activity (Flavell, Miller, & Miller, 1993). This is partly due to the fact that research on metacognition has focused on school-aged children's knowledge of cognitive processes, in an effort to understand which variables affect children's performance on school tasks, whereas studies on mind understanding under the rubric of ToM are mainly interested in investigating processes underlying children's social behavior (Flavell, 2000).

In this article, our interest is directed toward disentangling the relation between these two components of children's knowledge about the mind by examining the relative and differential influence of children's cognitive and emotion mental states knowledge on children's metacognitive knowledge about reading comprehension (i.e., metaknowledge about reading). We were especially interested in metaknowledge about reading as it directly relates to children's ability to comprehend text (Brown, Armbruster, & Baker, 1986; Orasanu, 1986; Paris, Cross, & Lipson, 1984) and is thus crucial for children's school success (Garner, 1987; Schoonen, Hulstijn, & Bossers, 1998). Metaknowledge about reading refers to knowledge about the nature of people as readers (such as their attitudes and individual differences), the nature of reading as a cognitive task (such as its different aims depending on readers'goals), and about possible strategies that can be applied to the task, as well as knowledge about different types of texts and their specific characteristics. Metaknowledge about reading strategies could include knowledge of the beneficial aspects of strategies such as skimming, gaining an overview of a text, and rereading.

Many thanks to the children who took part in this study and their parents and school staff for their interest and support of this project. We also would like to thank Ted Ruffman, Henry Wellman, and a second anonymous reviewer for their extremely helpful comments on previous versions of this article.

Correspondence concerning this article should be addressed to Serena Lecce, Department of Psychology, University of Pavia, P.zza Botta 6, 27100 Pavia, Italy. Electronic mail may be sent to slecce@unipv.it.

Furthermore, in mature readers, metaknowledge about texts is indicated in their sensitivity to text genres and text difficulties (Orasanu, 1986). Next, we discuss the three main aims of the present article.

The Relation Between Metaknowledge About Reading and Children's Mental State Knowledge

As stated above, the first aim of this study was to investigate the existence of a relation between children's mental state knowledge and metaknowledge about reading. The relation between metaknowledge about reading and children's mental state can be better understood if we think that a critical aspect of children's mental state understanding is that mental states are representations of the world and as such, can misrepresent (Perner, 1991). This ability can be extended to an understanding that text is also a representation that can be interpreted by oneself or others in various ways such that one could misrepresent the intended meaning of a text (Kamavar & Homer, 2000). Thus, the extent to which children understand text as metarepresentational likely depends to a certain extent on their understanding that a text has an intended meaning. These insights potentially act as an important basis for individual differences in children's capacity to reflect on the process of understanding text. Given these considerations, we hypothesized a relation between children's mental state knowledge and their metaknowledge about reading. This view can be also supported by two more general considerations. First, children's metaknowledge, defined as knowledge about the nature of people as cognisers and about cognitive processes, comprises and presupposes a knowledge about mental states. In this vein, Wellman argued that metacognition can be viewed "as a large, multifaceted theory of mind" (Wellman, 1985, p. 29). Second, theoretically, children's mental state knowledge and their metaknowledge can be considered as two distinct components of the same construct (Kuhn, 1999, 2000; Wellman, 1985), situated in the larger theoretical construct of metaknowing (Baker, 1994; Day, Cordon, & Kerwin, 1989; Flavell, 2000; Kuhn, 2000). Under this umbrella concept, Kuhn (2000) has further distinguished between *metacognitive knowing* or a declarative knowing, that is, "I know that *I know*" versus procedural knowledge or *metastrategic knowing*, which focuses on the impact of cognitive processes on-task performance, or "I know *how*."

The Specificity of the Relation Between Children's Mental State Knowledge and Their Metaknowledge About Reading

Our second goal was to investigate the specific type of mental state knowledge that would be related to children's metaknowledge about reading by comparing children's cognitive versus emotion mental state knowledge. To address this question, we analyzed four distinct aspects of children's mental state knowledge: cognitive state words (CSW), cognitive inference, emotion state words, and emotion understanding. We considered the first two variables (CSW and cognitive inference) as measures of children's cognitive mental state knowledge and the last two (emotion state words and emotion understanding) as indices of children's emotion mental state knowledge.

The rationale for investigating the differential link between cognitive versus emotion mental state knowledge and metaknowledge about reading comes from a growing body of research showing that (a) when language and background variables are taken into account, the association between children's cognitive and emotion understanding (Cassidy, Werner, Rourke, Zubernis, & Balaraman, 2003; Cutting & Dunn, 1999) and between cognitive and emotion state words (ESW) (Hughes, Lecce, & Wilson, 2007) disappears, and (b) cognitive and emotion understanding show distinct antecedents, correlates and sequelae (Cutting & Dunn, 1999; Dunn, 1995; Dunn, Brown, Slomkowski, Tesla, & Youngblade, 1991; McElwain & Volling, 2002). For example, whereas early emotion understanding is related to later positive peer experience (Denham, McKinly, Couchoud, & Holt, 1990), early cognitive understanding is associated with later negative perception of school (Dunn, 1995).

Distinguishing between cognitions and emotions is particularly important with respect to metaknowledge about reading because in order to represent their minds working with written sentences or passages, reading aloud and silently, and asking or answering questions, children should take special advantage from being familiar with cognitive mental representations and with cognitive state terms. Furthermore, children's ability to reflect on how their own minds work when reading, seems to presuppose a familiarity with terms that refer to cognitive activities (which we measured through the frequency of cognitive state talk) and to require the skill to reflect on cognitions (which we measured through cognitive inferences). Therefore, we hypothesized that children's cognitive mental state knowledge would have a stronger relation with metaknowledge about reading than their emotion mental state knowledge.

The Direction of the Relation Between Children's Mental State Knowledge and Their Metaknowledge About Reading

In line with the above proposal our last goal examined the prediction that children's mental state knowledge helps them develop their metaknowledge about reading. There are several reasons for positing a predictive relation between children's knowledge about mental states and their metaknowledge about reading. First, Kuhn (2000) proposed that moving from a knowledge of mental states in others to being able to reflect on higher order cognitive processes reflects a developmental progression that continues to develop into adulthood. We propose such a progression with respect to the development of children's metaknowledge of reading. Second, children approach the experience of learning to read at 5–6 years of age when they have already acquired a good knowledge about mental states. For example, they understand false beliefs and can distinguish mental states from real-life events (Wellman et al., 2001). The understanding that mental states can be different from reality is a critical step in children's developing knowledge about the mind and is likely to affect their metaknowledge about reading. Understanding that text can be interpreted in a variety of ways might provide insight into metastrategic knowledge, that is, that there are a variety of processes involved in understanding text. Indeed, when children come to understand that mental states and mental representations are not a simple copy of reality, they start to reflect on how their mind works in other cognitive tasks (Kuhn, 2000). Consistent with this view, preschoolers have limited awareness of the occurrence and the content of thinking (Flavell, Green, & Flavell, 1998, 2000). Finally, knowing about the cognitive processes involved in text comprehension (metaknowledge about reading) presupposes knowing about the components of that process (that the writer has an intended meaning that may or may not be grasped by the reader). Thus, having a concept of mental states provides a foundation for thinking about those states and their relation to cognitive tasks (Bartsch & Estes, 1996).

In order to address these three main goals we designed two studies. Study 1 examined the concurrent relation between metaknowledge about reading and mental state knowledge. Study 2 addressed our final two goals and is outlined in more detail after the results of Study 1. Both studies focus on school years when children's mental state knowledge becomes more sophisticated (Brown et al., 1986; Carpendale & Lewis, 2006) and metacognitive knowledge starts to develop in relation to reading comprehension. Thus, although by school age most children would have already passed first order false belief tasks, there are still strong individual differences in their tendency to refer to mental states to explain others' behaviors (Brown et al., 1986; Fox, 1991; Meins, Fernyhough, Johnson, & Lidstone, 2006; O'Connor & Hirsch, 1999). Our interest was in examining how this individual variation might relate to metaknowledge of reading.

Study 1

Study 1 addressed the first goal examining the *existence* of a relation between children's mental state knowledge and their metaknowledge about reading. In addition, we considered language and reading comprehension as potential mediators of this relation. There is a general consensus that children's verbal abilities and reading comprehension significantly correlate with their mental state knowledge (e.g., Cutting & Dunn, 1999; Hughes & Dunn, 1997; Hughes, Fujisawa, Ensor, Lecce, & Marfleet, 2006; Pelletier & Astington, 2004) and metaknowledge (Garner, 1987; Lockl & Schneider, 2007). Thus, we were interested in the relation between mental state knowledge and metaknowledge about reading over and above the effects of language and comprehension abilities. However, as stated above, we hypothesized that this would not be entirely mediated by language and reading comprehension.

In this first study we examined two age groups: 7 years and 9 years. We chose these age groups because previous research showed that they differ in their mental state knowledge (Antonietti, Liverta-Sempio, Marchetti, & Astington, 2006; Carpendale & Lewis, 2006) and metaknowledge about reading (Orasanu, 1986), with 9-year-olds showing a better understanding of mental states and a more mature knowledge of reading goals and simple strategies. We were, therefore, interested in comparing a younger and older age group in order to determine if school experience was a factor in the purported relation.

In Study 1 (as well as in Study 2), we used children's mental state words (MSW) produced in a written narrative task as a measure of their mental state knowledge. Children were asked to write an ending for two mentalizing stories concerning episodes of daily life, in which they needed to input a false belief (Story 1) and different beliefs (Story 2) in order to understand the situation described in the stories. Narratives offer an important opportunity to organize social experience (Bruner, 1986) and reflect on mental states (Dyer, Shatz, & Wellman, 2000), and as such are a useful way of investigating individual differences. At least two other studies (Camaioni, Longobardi, & Bellagamba, 1998; Fox, 1991) have adopted a written procedure asking children to produce stories that were then coded for MSW. The frequency of MSW is an important marker of individual differences in children's mental state knowledge and a good index of psychological understanding (Bartsch & Wellman, 1995; Hughes & Dunn, 1998; Hughes et al., 2007). Furthermore, as Peterson and Slaughter (2006) pointed out, the analysis of MSW in narratives allows the "exploration of individual differences in the use children make of their ToM capacities in populations from whom the false belief test is no longer informative" (p. 174).

Children's metaknowledge about reading was assessed by a questionnaire largely and successfully used in the Italian context to examine individual differences in metaknowledge both in typical and atypical development (see, e.g., Cornoldi, De Beni, & Pazzaglia, 1996; Kolić-Vehovec & Bajšanski, 2007; Pazzaglia, Cornoldi, & Tressoldi, 1993). For the purposes of the present study we selected age-appropriate subtests assessing children's understanding of the purpose of reading and strategies for reading (De Beni & Pazzaglia, 1994; Orasanu, 1986; Pazzaglia, De Beni, & Cristante, 1994). Both subtests reflect what Kuhn (2000) refers to as metastrategic knowing, that is, knowledge of how the mind works when performing a cognitive task.

Method

Participants

One hundred and ninety-six Italian children (92 boys and 104 girls), predominantly White, took part in this study. Of these, 90 attended second grade and 106 fourth grade in schools in the North of Italy. The schools were located in areas with mixed socioeconomic backgrounds. Children attending second grade (47 boys and 43 girls) had a mean age of 7.9 years (*SD* = 0.49, range = 6.3–10.25 years). Children attending fourth grade (44 boys and 61 girls) had a mean age of 10.1 years (*SD* = 0.40, range = 9.5–11.58).

Materials and Procedure

Children were administered a standardized test of metaknowledge about reading (reading goals and reading strategies), a mental state knowledge task (MSW), a standardized vocabulary task, and a reading comprehension task. All tasks were administered at school during two morning sessions of 30 min each. The order of the tasks was fixed. During the first session, children were administered first the vocabulary task and then the metaknowledge about reading task. In the second session, children were administered the story task first and then the reading comprehension task. Although the majority of the children had complete data, some of them did not complete all tasks. Eleven children did not complete the story task and the verbal ability (VA) task. Thirty-one did not complete the metaknowledge about reading questionnaire and the text comprehension task. Therefore, the numbers of children examined in individual analyses varied slightly. No age, $t(177) = 1.06$, *ns*, or gender, $\chi^2(1, 194) = 0.97$, *ns*, differences were found between children who completed all the tasks and those who gave missing data.

Children's metaknowledge about reading. This measure was assessed through the subtests of metaknowledge about reading goals (10 items) and reading strategies (10 items) from the Pazzaglia, De Beni, and Cristante's (1994) Metacomprehension Questionnaire. The reading goals subtest examines children's ability to understand that comprehension (and not decoding) is the main aim of reading and that it is possible to read for different reasons (e.g., for pleasure, for studying, for seeking specific information). The reading strategies subtest assesses children's knowledge of different reading strategies (e.g., rapid view of the text, analytic and selective reading, rereading) and their ability to use the appropriate strategy, depending on reading purpose and on materials. Children were credited with 1 point for each correct answer; therefore, possible scores range from 0 to 10 for both subtests. Cronbach's alphas for these scales were acceptable (αs = .74 and .64, respectively). Examples of items are given in the Appendix.

Mental state knowledge. Participants were asked to write an ending for two mentalizing stories concerning episodes of daily life. The first story concerned school life and required the child to impute a false belief; the second story concerned free time and required an understanding of different beliefs (see the Appendix). No time limit was set. Written answers were then coded for the frequency of MSW according to a list of mental state terms previously selected in other studies (Hughes et al., 2007). Examples of the coding categories are given in the Appendix. Each reference to a mental state was summed into a total MSW score. Subsequent repetitions of the same mental state term (i.e., ''She thinks and re-thinks . . .'') and comments that were extraneous to the narratives (i.e., ''I don't know''; ''I like this story'') were excluded. Two researchers independently coded 20% of the stories. Interrater agreement, established using Cohen's kappa, was excellent ($\kappa = .86$). We were interested in the raw number of children's references to mental states rather than the proportion. As Ruffman and colleagues argued (Ruffman, Slade, & Crowe, 2002), each mention to an inner state potentially reflects child's own tendency to refer to mental states to explain other's behavior. In order to control for story length, we calculated the total number of words (excluding mental state terms) in the story and created a nonmental state words (NMSW) total score. As in Ruffman et al. (2002) and Peterson and Slaughter (2006), we considered this variable (NMSW) as a measure of children's expressive language.

Verbal ability. The NMSW score from the story task was used to assess children's expressive language. Children's receptive language was measured using the Italian version of the vocabulary subtest of the Primary Mental Abilities (PMA; Thurstone & Thurstone, 1962; Rubini & Rossi, 1982). This test required children to find the synonym of a target word choosing between four alternative words (30 verbal items), and to match a picture to a word read by the researcher choosing between four alternatives (30 picture-matching items). A time limit of 5 min was set. Performance was evaluated in terms of the number of correct answers. Reliability was good for both subscales (Cronbach's alphas = .83 and .93, respectively).

Reading comprehension task. Two parallel stories, one for second and one for fourth graders from the memory and transfer (MT) standardized reading comprehension battery (Cornoldi & Colpo, 1995) were administered. Research carried out on these age groups has demonstrated good test validity and reliability (for a review, see Cornoldi & Colpo, 1995; Palladino, De Beni, & Cornoldi, 1995). Participants were required to read silently and answer a series of multiple-choice questions, the final score being the number of correct answers. All questions probed inferential information, (e.g., main idea, cause–effect relation, implied meanings) rather than literal information. The procedure allowed participants to have the passages in front of them in order to consult them during the answering phase. No time limit was imposed. Possible scores range from 0 to 10 points. Cronbach's alpha was acceptable, $\alpha = .68$.

Results

We begin by presenting data reduction and descriptive statistics for reading comprehension, receptive and expressive language, metaknowledge about reading and MSW. Before describing associations between variables, we summarize findings concerning age and gender effects. For all correlation analyses between metaknowledge about reading and MSW, we controlled for both receptive and expressive language as well as for reading comprehension.

Data Reduction

The two subtests of metaknowledge, goals of reading and reading strategies, were correlated with each other both in second graders, $r_{\mathrm{II}}(74) = .34$, $p < .01$, and fourth graders, $r_{\mathrm{IV}}(87) = .31$, $p < .01$. Therefore, the scores on the two subtests were summed into an overall index of metaknowledge about reading. Reliability for this aggregate was satisfactory, $\alpha = .66$. Regarding the receptive vocabulary measure, children's performance on the verbal and figural items of the PMA were highly associated both in second graders, $r_{\mathrm{II}}(86) = .46$, $p < .001$, and fourth graders, $r_{\mathrm{IV}}(95) = .57$, $p < .001$. Therefore, an aggregate index of children's receptive vocabulary was created by summing scores on the verbal and figural items. Cronbach's alpha for this overall score was .93, indicating excellent internal consistency. Finally, the frequencies of children's MSW used in the two stories were significantly related to each other, $r_{\mathrm{II}}(86) = .49$, $p < .001$; $r_{\mathrm{IV}}(95) = .33$, $p < .001$. Similarly, the score of NMSW in Story 1 significantly related to the score of NMSW in Story 2, $r_{\mathrm{II}}(86) = .75$, $p < .001$; $r_{\mathrm{IV}}(95) = .79$, $p < .001$. Therefore, aggregate MSW and NMSW scores were created by summing children's scores on the two stories.

Descriptive Statistics

Table 1 presents the means and standard deviations for all raw scores. Next, we conducted a series

Table 1

Descriptive Statistics for Study 1 Measures in Second and Fourth Graders

	M (*SD*) for second graders	*M* (*SD*) for fourth graders	*t*	*df*
Reading comprehension	6.68 (2.49)	7.14 (2.12)	1.27	163
Receptive vocabulary	32.03 (8.66)	41.22 (5.87)	8.51**	183
Nonmental state words (NMSW)	86.41 (55.82)	245.76 (99.02)	11.24**	182
Metaknowledge about reading	9.63 (3.27)	13.25 (2.48)	8.07**	163
Mental state words (MSW)	1.35 (1.65)	3.99 (2.66)	8.00**	183

$^{**}p < .01$ (all significance tests are two-tailed).

of *t* tests to examine effects of age (second versus fourth grade) and gender on children's receptive vocabulary, NMSW, metaknowledge about reading, and MSW. Analyses showed significant main effects of age on all these variables, with fourth graders reporting higher scores than second graders (see Table 1). No significant gender differences were found for three of four variables. The only exception was MSW, $t(181) = 2.59$, for which girls ($M = 3.19$, $SD = 2.7$) showed higher levels than boys ($M = 2.2$, $SD = 2.3$). However, the effect size, $\eta^2 = .03$, suggests that this difference should be reexamined with a larger sample size.

Relation Between Metaknowledge About Reading, Language, and MSW

Table 2 presents the zero-order correlations between age, reading comprehension, receptive vocabulary, NMSW, MSW, and metaknowledge about reading for the sample as a whole and for the second and fourth graders considered separately. As expected, for the total sample, children's age, reading comprehension, and language (both receptive and NMSW) were significantly interrelated and were associated with MSW and metaknowledge about reading. Children who were older and who reported higher scores on language and reading comprehension had a more mature metaknowledge about reading and produced higher frequencies of MSW. Interestingly, the association between metaknowledge about reading and the frequency of MSW was significant even after controlling for receptive vocabulary and NMSW, $r(156) = .19$, $p < .05$; reading comprehension, $r(151) = .39$, $p < .01$; and age, $r(148) = .29$, $p < .01$. When language, reading comprehension and age were controlled together, the correlation between metaknowledge about reading and MSW still approached significance, $r(135) = .16$, $p < .06$. In other words, children who often referred to the characters' mental states were also more likely to

Table 2

Study 1 Zero-Order Correlations Between Study 1 Measures in the Sample Overall and in Second and Fourth Graders Considered Separately

Subscale		Age	RC	RVoc	NMSW	MSW	MKR
Age	All	–	.19*	.54**	.68**	.50**	.45**
	2nd graders		.15	.02	.12	.02	.15

obtain higher scores on the Metacomprehension Questionnaire and vice versa. Furthermore, the pattern of correlations shown in Table 2 was very similar for second and fourth graders when examined separately. The main exception was the lack of associations with age. At first glance, this result is surprising; however, note that within each sample the variability in age was restricted.

In order to be sure that children's MSW and NMSW can be considered as two distinct variables, with distinct implications, we also computed a partial correlation between NMSW and metaknowledge about reading, removing the influence of MSW. Interestingly, this partial correlation was not significant, supporting our view that the NMSW variable is a measure of linguistic competence and MSW variable in itself is indeed the crucial index of children's mentalizing abilities.

To summarize, our analyses showed a significant and positive association between second and fourth graders' use of MSW and their metaknowledge about reading, independent of language and reading comprehension.

Discussion

The main aim of Study 1 was to investigate the relation between two domains of children's knowledge about the mind, metaknowledge of reading and mental state knowledge. The critical finding of this study was the significant association between children's metaknowledge about reading and their mental state knowledge as indexed by the tendency to use MSW when completing two stories (specifically chosen so as to include a mentalistic prompt). That is, children who understand that there may be different goals when reading and who can recognize the correct strategies according to the specific task presented, tended to use MSW more frequently in a written story task. Interestingly, this result was found in second and fourth graders, indicating that although performance on tasks assessing both constructs develops significantly between second and fourth grade, as reported in the literature (Carpendale & Chandler, 1996) and in our own data, the link between the two does not seem to change. Thus, our data support the view of a consistent relation between metaknowledge about reading and MSW that is only partially due to VA and reading comprehension. Results from Study 1 fit well with the theoretical framework proposed by Kuhn (1999, 2000) in which mental state knowledge and metacognition are viewed as distinct skills as part of a general ability of "meta-knowing" in which children reflect on their own and other's minds and cognitive processes. They are also consistent with those of Lockl and Schneider (2007), who demonstrated that 4- and 5-year-old children's performance on false belief tasks was associated with their knowledge about memory processes when they were nearly 6.

Although informative and novel, Study 1 had a number of weakness concerning the measure of mental state knowledge. In Study 2, we differentiated between children's cognitive versus emotion mental state knowledge. Although understanding the mental states of others encompasses an understanding of beliefs and knowledge as well as multiple internal states such as desires and emotions (Dunn, 1995; Wellman & Liu, 2004), a growing body of research shows a lack of relation between concurrent cognitive and emotion understanding when language and background variables are taken into account (Cassidy et al., 2003; Cutting & Dunn, 1999; Hughes et al., 2007). To date, however, no study has directly compared concurrent and longitudinal associations between cognitive versus emotion mental state knowledge and metacognitive knowledge. Thus, the first aim of this study was to examine whether cognitive and emotion understanding showed a similar pattern of associations with metacognitive knowledge. Consistent with those studies presented above demonstrating an independence between children's cognitive and emotion understanding and the close link between children's false belief and metacognition, we hypothesized that metacognitive knowledge would be more strongly related to their knowledge about cognitive than emotional mental states.

More important, although Study 1 demonstrated a clear relation between children's mental state knowledge and metaknowledge of reading, its cross-sectional nature meant that we could not be confident that the influence of mental state knowledge on metacognitive knowledge was indeed a causal one. Study 2 was therefore, designed to expand on the findings of Study 1 using a longitudinal design to examine the direction of influence between these two constructs. To this end, we measured mental state knowledge and metaknowledge about reading at two time points. This methodological design allowed us to directly compare two models: the first one (Model A) in which early mental state knowledge predicted later metaknowledge, and the second one (Model B) in which early metaknowledge predicted later mental state knowledge. In order to control for the mediating role of VAs, we covaried children's receptive and expressive language. We did not include children's reading comprehension as a covariate as we found it in Study 1 to play a minor role in the association between mental state knowledge and metaknowledge of reading. Furthermore, in Study 2 the measure of metaknowledge was expanded by pairing a second standardized measure with the questionnaire of metacomprehension to improve the reliability of the measure and to include measures of metaknowledge related to a broader range of school tasks.

Study 2

Method

Participants

In total, 71 children (37 boys and 34 girls) took part in this longitudinal study. None of these children had been previously involved in Study 1. Children were all White and Italian speaking and were recruited from two primary schools with socially mixed catchment areas in the North of Italy. All children had written parental consent to participate and were tested at two time points, separated by a testing interval of approximately 11 months. Children's mean age was 10 years (*SD* = 0.54, range = 9.08–11.16 years) at Time 1 and 10 years 11 months (*SD* = 0.49, range = 10–12 years) at Time 2. Children with learning disabilities were excluded. All 71 children took part in the study at both time points.

Materials and Procedure

At each time point, children participated in two group sessions and in an individual session. The order of the tasks within each session was fixed. In the first group session children were administered the metaknowledge about reading task followed by the story task. The second group session consisted of the Strange Stories task, the Questionnaire of Metacognition and the vocabulary task. In the individual session children's emotion understanding on the Test of Emotion Comprehension (TEC) was evaluated.

Metaknowledge about reading and school tasks. At each time point, children's metaknowledge was assessed via two age-appropriate subtests from the Metacomprehension Questionnaire, as in Study 1 (Pazzaglia et al., 1994), and the Questionnaire of Metacognition (Friso, Palladino, & Cornoldi, 2006).

In the Metacomprehension Questionnaire children were administered the knowledge of reading strategy subtest (10 items) and the text sensitivity subtest (12 items), as they are the most discriminative aspects of metaknowledge on reading at this age (De Beni & Pazzaglia, 1994; see the Appendix for examples). For details on the reading strategies subtest, see Study 1. The text sensitivity subscale was made up of 12 items evaluating children's ability to classify some features of a text according to an importance order, to indicate literary genders (e.g., fairy tale, article, and drama), to evaluate the relative difficulties of two different texts, and to use the title of a text to anticipate its content. Children were credited with 1 point for each correct answer; therefore, possible scores range from 0 to 12 points. Cronbach's alphas for these scales were acceptable ($\alpha = .69$ for reading strategy and $\alpha = .72$ for text sensitivity).

The Questionnaire of Metacognition has been recently developed within a metacognitive training program for primary school children (Friso et al., 2006). It assesses children's metaknowledge not only in relation to the specific context of reading but also to other school tasks such as studying and problem solving. It consists of 15 items tapping different aspects of metaknowledge: the concept of mind, knowledge of strategies in typical learning situations (such as reading, writing, and counting), and knowledge related to control and monitoring. Children were asked to read all the questions silently and to choose the correct answer from four alternatives. No time limit was imposed. One point was given for each correct answer; thus, possible scores ranged from 0 to 15 points. Internal consistency was acceptable (Cronbach's alpha = .68). Examples of some items are given in the Appendix.

Cognitive mental state knowledge. At both time points, children's cognitive understanding was assessed through the Strange Stories task (Happè, 1994) and the frequency of CSW in the story task of Study 1. For time reasons, we included only one of the two stories used in Study 1. We chose Story 1 as it was found to be the one that elicited the highest frequency of MSW (see Study 1 for details on coding).

The Strange Stories task is an advanced test of ToM that assesses the ability to make inferences about mental states by interpreting nonliteral statements (Happè, Winner, & Brownell, 1998; Maylor, Moulson, Muncer, & Taylor, 2002). We selected a subgroup of six mentalistic stories involving cognitive mental states. They included two double bluffs, two mistakes, and two pretence stories. All stories were followed by two questions; a comprehension question ("Is it true what X says?") and a justification or mental state question ("Why does X say this?''). Children were asked to carefully read the stories for themselves and then write the answers; no time limit was set. Justification answers were scored according to their references to mental versus physical states. In line with other studies (Happè et al., 1998; Sullivan & Ruffman, 2004), answers were scored according to a 0–2 scale, giving 0 for an incorrect or did not know answer, 1 for partial or implicit correct answers, and 2 for full and explicitly correct answers. Internal consistency for this measure was good (Cronbach's alpha = .81). An example of the scoring criteria is given in the Appendix. Interrater agreement with the second author, established using Cohen's kappa, was good (κ = .82).

Emotion mental state knowledge. At both time points, emotion understanding was evaluated via the frequency of ESW produced in the story task (see Study 1) and the Italian version of the TEC (Albanese & Molina, 2008).

The TEC is an extensive measure of emotion comprehension in children between 3 and 11 years of age (Pons, Harris, & de Rosnay, 2004). The TEC gives an overall score of emotion understanding evaluating nine components with a hierarchical organization (for more details on these nine components, see the Appendix). It consisted of an A4 picture book with a simple scenario on each page. While showing each picture scenario, the experimenter read the accompanying story with a neutral tone of voice. After hearing the story, children were asked to attribute an emotion to the main character (whose face was blank) by pointing to one of four alternative emotional outcomes depicted below the scenario (two negative and two nonnegative emotions). One point was given for each component correctly answered. Scores ranged between 0 and 9. Cronbach's alpha for this scale was .84.

Verbal ability. As in Study 1, children's receptive language was assessed via the Vocabulary subtest of the PMA (Thurstone & Thurstone, 1962) and children's expressive language was assessed via the total NMSW produced in the story task. The same tasks were administered at both time points. In this study, because of time constraints, we only administered the verbal scale of the Vocabulary subtest. A time limit of 4 min was set. The reliability was good, Cronbach's alpha = .87.

Results

We first present preliminary analyses concerning (a) data reduction and descriptives, (b) developmental changes and stability for all variables, (c) associations between cognitive (Strange Stories, CSW) and emotion mental state knowledge (TEC and ESW), and (d) associations between language and both mental state knowledge and metaknowledge about reading. In the Results section, we address the two focal issues of this study, the specificity and the direction of the relation between children's mental state knowledge and metaknowledge about reading, presenting correlations and hierarchical regression analyses within and between time points. As in Study 1, we give zero-order (in Table 4) as well as partial correlations (in the text) controlling for both receptive and expressive language.

Data Reduction

Children's scores on the two areas of metaknowledge about reading from the Metacomprehension Questionnaire, goals of reading and reading strategies, and on the Questionnaire of Metacognition were significantly associated both at Time 1, mean $r(69) = .46$, rs ranged from .41 to .50, $p < .01$, and at Time 2, mean $r(69) = .33$, rs ranged from .28 to .37, $p < .01$. Therefore, we calculated children's percentages of success in each questionnaire and then averaged these percentages to create an overall measure of metaknowledge. This aggregate showed good internal consistency, Cronbach's alpha = .71.

Descriptive Statistics and Developmental Changes and Continuities

Table 3 shows the descriptive statistics for the study measures at both time points. In order to examine changes across time, we conducted seven paired-sample t tests, applying Holm's correction to maintain familywise error at 0.05. There were significant age-related increases in receptive vocabulary, NMSW and the TEC. No time effect was found for children's references to emotions (ESW), Strange Stories, and metaknowledge about reading, and a significant difference, but in the opposite direction, was found for children's reference to cognitive states (CSW).

Table 4 presents the zero-order concurrent and longitudinal correlations between, language, cognitive mental state knowledge, emotion mental state knowledge, and metaknowledge about reading. The correlations between Time 1 and Time 2 indicate good stability over time for receptive and expressive language, cognitive mental state knowledge (both Strange Stories and CSW), TEC, and metaknowledge about reading, mean $r = .36$, $p < .01$.

Associations Between Cognitive and Emotion Mental State Knowledge

Overall, the pattern of correlations in Table 4 indicated that 9 of 16 correlations between cognitive and emotion mental state knowledge were not significant. When we controlled for receptive and expressive language, however, there were no significant associations, with the exception of the correlation between Time 1 Strange Stories and Time 2 ESW, $r(67) = .28$, $p < .05$. These results support the view of an independence between cognitive and emotion mental state knowledge. Therefore, they will be considered separately in the following analyses. Here, it is also important to note that the associations between CSW and the Strange Stories measures were significant, highlighting the validity of our measures. In contrast, no associations were found between children's frequency of ESW in the story task and their ability to infer others' emotions on the TEC.

Table 3

Descriptive Statistics of Key Measures of Study 2 at Time 1 and Time 2

	Time 1 *M* (*SD*)	Time 2 *M* (*SD*)	*t*	*df*
Receptive vocabulary	25.96 (5.25)	28.38 (2.82)	4.67**	70
Nonmental state words (NMSW)	68.80 (34.51)	88.54 (22.49)	4.63**	70
Strange stories	4.49 (1.71)	4.92 (1.73)	2.03	70
Cognitive state words (CSW)	2.45 (2.02)	1.77 (1.38)	−2.69*	70
Test of emotion comprehension (TEC)	7.23 (1.13)	7.78 (1.06)	2.35*	70
Emotion state words (ESW)	1.67 (1.45)	1.69 (1.45)	.06	70
Metaknowledge about reading	0.67 (0.11)	0.70 (0.11)	−1.97	70

*p < .05. **p < .01 (all significance tests are two-tailed).

Associations Between Language, Mental State Knowledge, and Metacognitive Knowledge

Table 4 also shows the correlations between language, mental state knowledge and metaknowledge about reading. Individual differences in children's receptive vocabulary and NMSW were not significantly associated to one another within time points and showed a different pattern of correlations with the four mental state knowledge measures. At both time points, children's NMSW was associated with the frequency of cognitive, $rs(69) \geq .22$, $ps < .05$, and

Table 4

Zero-Order Correlations Between Key Measures of Study 2 Within and Across Time

		Time 1							Time 2						
		RVoc	NMSW	SS	CSW	TEC	ESW	MKR	RVoc	NMSW	SS	CSW	TEC	ESW	MKR

*p < .05. **p < .01 (all significance tests are two-tailed).

emotion words, *rs*(69) ≥ .23, *ps* < .05, as well as metaknowledge about reading, *rs*(69) ≥ .22, *ps* < .05. On the other hand receptive vocabulary seemed to play a minor role, correlating with metaknowledge about reading within and across time, *rs*(69) ≥ .30, *ps* < .01, yet only with CSW at Time 1 and the TEC at Time 2. Having found that VA was, at least in part, associated with mental state knowledge and metacognitive knowledge, we also controlled for VA in subsequent analyses.

Concurrent Relations Between Mental State Knowledge and Metaknowledge About Reading

We first checked whether we could replicate the results of Study 1 with a different sample and in slightly older children. As in Study 1, partial correlations controlling for language between children's frequency of MSW and their metaknowledge were significant, $r(67) = .26$, $p < .05$ at Time 1 and $r(67) = .31$, $p < .01$ at Time 2. In addition, the relation between NMSW and metaknowledge controlling for MSW was, as in Study 1, not significant at both time points, *rs*(67) ≤ .14, *ns*.

Study 2 was designed to examine whether children's cognitive and emotion mental state knowledge differentially related to their level of metaknowledge about reading. Table 4 shows a different pattern of correlations depending on the time point considered. At Time 1, the relation between metaknowledge about reading and mental state knowledge seems to be different depending on the type of mental state considered. Only cognitive mental state knowledge (both the Strange Stories and CSW), *rs*(69) ≥ .25, *ps* < .05, and not emotion mental state knowledge, *rs*(69) ≤ .12, *ns* (both the TEC and ESW) was positively associated with children's scores on the Metacognitive Questionnaire even after controlling for individual differences in VAs, $r(67) = .24$, $p < .05$. By contrast, at Time 2, metaknowledge about reading was found to be significantly related to both cognitive and emotion mental state knowledge, even after controlling for VAs, $r_{\text{CSW}}(67) = .23$, $p < .05$; $r_{\text{TEC}}(67) = .29$, $p < .05$.

Longitudinal Relation Between Mental State Knowledge and Metaknowledge

A core aim of Study 2 was to examine the direction of the relation between children's mental state knowledge and their metaknowledge about reading, comparing two opposite models: Model A, in which early mental state knowledge predicts later metaknowledge, and Model B, in which early metaknowledge predicts later mental state knowledge. In order to investigate this issue we performed correlations and hierarchical regression analyses.

Model A. Table 4 shows that at Time 1 both measures of cognitive mental state knowledge were significantly related to Time 2 metaknowledge about reading, *rs*(69) ≥ .31, *ps* < .01. In contrast neither the TEC nor ESW at Time 1 were related to Time 2 metaknowledge of reading. In order to examine the predictive effect of early cognitive mental state knowledge on later metacognitive knowledge, we computed a hierarchical regression analysis (see Table 5). Given the robust correlations between children's scores on CSW and Strange Stories, we aggregated the two measures into an overall index of cognitive mental state knowledge. Time 2 cognitive mental state knowledge aggregate was log transformed in order to reduce any effects of the positive skew that was apparent in the raw data. We entered Time 1 language (receptive vocabulary and NMSW) and metaknowledge about reading at Step 1 and the Time 1 cognitive mental state knowledge composite at Step 2 to establish whether it made a significant independent contribution in

Table 5

Hierarchical Regression Analysis Examining Time 1 Cognitive Mental State Knowledge as a Predictor of Metaknowledge About Reading at Time 2 Controlling for Verbal Abilities and Metaknowledge About Reading at Time 1

	Variable	*B*	*SE B*	ß
Step 1	Vocabulary Time 1	.01	.01	.14
	NMSW Time 1	.01	.01	.12
	Metaknowledge about reading Time 1	.44	.12	.43**
Step 2	Vocabulary Time 1	.01	.01	.09
	NMSW Time 1	.01	.01	.06
	Metaknowledge about reading Time 1	.38	.11	.37**
	Cognitive mental state knowledge Time1	.02	.01	.25*

Note. $R^2 = .28$ for Step 1; $\Delta R^2 = .05$ for Step 2. NMSW = nonmental state words.
**p* < .05. ***p* < .01 (all significance tests are two-tailed).

predicting variance in metaknowledge about reading at Time 2. Table 5 shows that at Step 1, Time 1 metaknowledge about reading was the only significant predictor, accounting for 28% of the variance in Time 2 metacognitive knowledge, $F(3, 67) = 9.43$, $p < .001$. The addition of Time 1 cognitive mental state knowledge significantly improved the amount of variance explained, $\Delta R^2 = .05$, $F(4, 66) = 4.22$, $p < .001$. When the metaknowledge reading items and the metaknowledge of general school activity items were considered separately, the addition of Time 1 cognitive mental state knowledge in the second step still approached significance, $p < .08$ for both regressions.

We also conducted a second analysis to assess whether the effect of Time 1 cognitive mental state knowledge on Time 2 level of metaknowledge about reading was independent of the effect of Time 2 cognitive mental state knowledge. We, therefore, entered children's Time 1 language (receptive vocabulary and NMSW), metaknowledge about reading, and Time 2 cognitive mental state knowledge at Step 1 and Time 1 cognitive mental state knowledge composite at Step 2 of the regression (see Table 6). Step 1 was significant with early metaknowledge about reading and cognitive mental state knowledge being the only significant predictors, $R^2 = .22$, $F(4, 66) = 5.99$, $p < .001$. The addition of Time 1 cognitive mental state knowledge did significantly improve the amount of variance explained in the criterion variable, $\Delta R^2 = .04$, $F(1, 65) = 5.84$, $p < .05$. Interestingly, when we tested the opposite model in order to assess the effect of Time 2 cognitive mental state knowledge on concurrent (Time 2) level of metaknowledge about reading controlling for Time 1 cognitive mental state knowledge, language and metaknowledge about reading, Time 2 cognitive mental state knowledge did not significantly explain a unique percentage of variance in Time 2 metaknowledge about reading, $F(1, 65) = 1.44$, *ns*.

Model B. Table 4 also shows that Time 1 metaknowledge about reading is significantly related with Time 2 CSW and emotion comprehension. In order to better understand these relations, we performed two separate hierarchical regressions with Time 2 CSW and Time 2 emotion comprehension as dependent variables, respectively. In the first regression (Time 1 metaknowledge over Time 2 CSW), we entered Time 1 CSW and language in Step 1 and Time 1 metaknowledge about reading in Step 2. Neither Step 1, $F(3, 66) = 1.92$, *ns*, nor Step 2, $F(1, 65) = 1.03$, *ns*, was significant. In the second regression (Time 1 metaknowledge over Time 2 emotion understanding), we entered Time 1 emotion understanding and language at Step 1 and Time 1 metaknowledge about reading at Step 2. Results showed that Step 1 explained a significant 19% of the variance, $F(3, 66) = 6.28$, $p < .01$, with Time 1 emotion understanding and receptive vocabulary being significant predictors. However, Time 1 metaknowledge about reading did not significantly improve the amount of variance explained in the criterion variable, $\Delta R^2 = .04$, $F(1, 68) = 5.80$, *ns*.

In sum, the results of previous analyses provide support for Model A in which early mental state knowledge predicts later metaknowledge. The main finding of this second study was that there was a predictive relation between children's early cognitive (but not emotion) mental state knowledge and their later metaknowledge, even when continuities in metaknowledge and VAs were taken into account.

Table 6

Hierarchical Regression Analysis Examining Time 1 Cognitive Mental State Knowledge as a Predictor of Concurrent Metaknowledge About Reading at Time 2 Controlling for Verbal Abilities and Metaknowledge About Reading at Time 1 and Cognitive Mental State Knowledge at Time 2

	Variable	*B*	*SE B*	ß
Step 1	Vocabulary Time 1	.01	.00	.17
	NMSW Time 1	.00	.00	.14
	Metaknowledge about reading Time 1	.29	.12	.29*
	Cognitive mental state knowledge Time 2	.37	.18	.23*
Step 2	Vocabulary Time 1	.01	.00	.12

	Cognitive mental state knowledge Time 1	.02	.01	.26*

Note. $R^2 = .22$ for Step 1; $\Delta R^2 = .04$ for Step 2. NMSW = nonmental state words.
*$p < .05$ (all significance tests are two-tailed).

Discussion

The purpose of this second study was twofold. Our first goal was to examine the specificity of the link between mental state knowledge and metaknowledge about reading by distinguishing two components of children's mental state knowledge: cognitive and emotion mental state knowledge. Our second goal was to investigate the direction of the link between children's mental state knowledge and their metaknowledge about reading adopting a longitudinal design. The strengths of Study 2 are that, first, it allowed us to look at the predictive effect of mental state knowledge on later metaknowledge about reading. Second, it adopted a finer grain analysis of mental state knowledge. Third, it integrated the analysis of the use of MSW with more classic measures of mental state knowledge. Finally, it included additional measures of metaknowledge about reading.

Before discussing the main findings of Study 2 there are preliminary results that warrant discussion. First, it is important to note that, at least in part, findings of Study 2 replicated, in slightly older children, the results of Study 1. That is, children who referred more to mental states in the story task also reported higher scores on metaknowledge about reading tasks, independently of VAs. In other words, as expected on the basis of our first study, there was a significant amount of shared variance between children's understanding of how their own minds work in relation to school tasks and their tendency to interpret others' behavior in terms of mental states. Second, we observed stability across time in children's mental state knowledge and metacognitive knowledge, even when language was taken into account. This finding echoes those of similar studies that demonstrated stability of individual differences in children's emotion (Pons & Harris, 2005) and false belief understanding (Hughes & Dunn, 1998) and in their beliefs about themselves as readers (Bouffard, 1998). Third, there were few significant associations between mental state knowledge and language. Although this finding needs further replication, we suggest that it could reflect the age of our sample. Indeed, previous research shows that individual differences in MSW and language are strongly associated in preschoolers (Bretherton & Beeghly, 1982; Hughes et al., 2006) but not in school-aged children and adolescents (Meins et al., 2006; O'Connor & Hirsch, 1999). Therefore, it is likely that the association between mental state knowledge and language shows a developmental trajectory.

The first main aim of this study was to investigate the specific link between mental state knowledge and metaknowledge about reading by examining children's cognitive versus emotion mental state knowledge. Motivation for this comparative analysis was confirmed with the finding that, with the exception of the relations between Strange Stories and emotion understanding at Time 1, there were no significant correlations between cognitive and emotion mental state knowledge at both time points. This result fits with studies on younger children (see the Introduction) and with neuroimaging studies reporting distinct anatomical correlates for understanding of thoughts versus feelings (see Saxe, Carey, & Kanwisher, 2004).

Regarding the specificity of the relation, the present study showed a differential relation between cognitive mental state knowledge and children's metaknowledge about reading. That is, as we predicted, the predictive effect of early mental state knowledge on later metaknowledge about reading was found only for cognitive and not for emotion understanding. We argue that the close and specific connection between children's understanding of cognitions and metaknowledge reflects the conceptual link between the two domains. As we have said in the Introduction, children's knowledge of how their minds work when reading presupposes a familiarity with terms indicating cognitive activities and also requires the ability to infer and to reflect on cognitions. On the other hand, children's metaknowledge about reading does not necessarily require a knowledge of emotional states, which seems to be more relevant for social aspects of school readiness (Denham, 2006).

Besides discussing the specificity of the relation, we believe that the lack of association between the two measures of children's emotion mental state knowledge, TEC and ESW, deserves further attention. From a methodological perspective, this result was unexpected and questioned the reliability of the emotions measures. However, it is important to note that children's scores on the TEC were stable across time and consistent with the age-appropriate findings reported in Albanese and Molina (2008) and Pons et al. (2004). Therefore, it is also possible that the lack of association between the TEC and ESW reflects a theoretical issue rather than a methodological concern. It could be explained by considering the difference between the TEC and the story task. Whereas the TEC assesses the level of possession of an ability, (i.e., competence), the production of emotion state terms evaluates children's spontaneous tendency to *use* an ability in interpreting social behavior. An intriguing possibility is that in school-aged children the tendency to focus on internal states can be independent from their capacity to represent those mental states. In line with this interpretation, Meins and colleagues recently argued that "children's proportional use of internal-state language in noninteractional contexts can be thought of more as a measure of children's *spontaneous use* of their ToM capacities than of those capacities themselves" (Meins et al., 2006, p. 193).

Although we find in line with our prediction that emotion mental state knowledge was not predictive of children's metaknowledge of reading, it is worth considering, however, whether other aspects of emotion development such as emotion regulation might have related. Emotion regulation is described as the capacity to modify, regulate or evaluate one's emotional reactions and is influenced by children's developing ToM as well as emotion understanding (see Thompson, 1994; Thompson, Lewis, & Calkins, 2008, for reviews). Furthermore, in older children, development in inhibitory control fosters increased emotion regulation through emotional self-management (Thompson et al., 2008). Since the regulation of emotion requires the development, not only of ToM but also awareness of the self-management of emotion, it is plausible that this skill could relate to ongoing developments in metacognition. This is a future research direction which requires further attention. It is also important to note that, although at Time 1 metaknowledge about reading was linked with cognitive mental state knowledge and not with emotion mental state knowledge, at Time 2 metacognition was equally related with these two areas of mental state knowledge. Therefore, given the predictive role of cognitive mental state knowledge on metacognition, correlates of metaknowledge about reading may change with time. Despite the lack of available data, it is possible that the link between mental state knowledge and metacognition is sensitive to development (Kuhn, 2000). In other words, it could be that being able to represent a cognitive mental state and having a concept of that state is fundamental for children's emerging understanding of how the mind works with respect to specific tasks. Later in development, when mental state knowledge and metacognitive knowledge become more sophisticated (e.g. Flavell, 2000; Perner, 2005), the exchange between the two could become less specific.

The second core aim of this study was to investigate the direction of the relation between children's mental state knowledge and their metaknowledge about reading. Our main results indicated that children's cognitive mental state knowledge, as assessed via the Strange Stories task and the frequency of cognitive state terms in a story task (but not their emotion mental state knowledge), significantly predicted later metaknowledge about reading even when we controlled for children's earlier metacognitive knowledge, receptive and expressive language and Time 2 cognitive mental state knowledge. In contrast, early metaknowledge about reading did not predict children's later mental state knowledge. Moreover, children's concurrent cognitive mental state knowledge did not explain metaknowledge when earlier cognitive mental state knowledge was controlled for. Taken together these results provide strong support for the causal relation between cognitive understanding and the development of metaknowledge relevant to school tasks. Therefore, early mental state knowledge can be considered a precursor of subsequent metaknowledge and can be seen as a step in a series of change in children's understanding of knowledge. In addition, although the questionnaire tasks we used in the present studies were selected to specifically focus on metaknowledge of reading, certain questions in the second Metacognitive Questionnaire did address other aspects of metacognitive understanding such as "remembering" and "writing." Preliminary results looking at these more general items suggest that our findings do extend to metacognitive awareness within other school tasks more generally, although this needs further research.

Our findings fit nicely with the argument that children's mental state knowledge is a prerequisite for the development of their metacognition (Bartsch & Estes, 1996; Wellman, 1985). In other words it seems that children's capacities to mentalize about reality and to infer cognitive mental states underlying social actions helps them understand how their own mind works in relation to metaknowledge of reading. On this view, children have to acquire an understanding of mental states before they can reflect on their own or on other people's cognitive activity (Perner, 2000), and a representation of the concept of mental state is necessary to develop the ability to think and regulate one's own mental activity in relation to a specific cognitive task (Bartsch & Estes, 1996). Our results are also consistent with prior studies that have showed significant relations between children's mental state knowledge and indirect measures of metaknowledge such as awareness of the interpretive character of the knowing processes (Carpendale &

Chandler, 1996), metacognitive vocabulary (Antonietti et al., 2006), and understanding that the teaching process depends on a knowledge difference between teachers and pupils (Astington & Pelletier, 1996; Ziv & Frye, 2004). Finally, the results of the present study provide support for Lockl and Schneider (2007) who argued that "theory of mind is a general cognitive tool able to influence cognitive processes in a variety of domains" (p. 164).

Conclusion

To summarize, this study examined school-aged children's capacity to reason about mental states by examining the concurrent and longitudinal relation between children's mental state knowledge and metaknowledge about reading. Generally speaking, results indicate that (a) there is a strong link between school-aged children's mental state knowledge and metaknowledge about reading, (b) the link between mental state knowledge and metacognition is causal and goes from earlier mental state knowledge to later metaknowledge about reading, (c) the link between earlier mental state knowledge and later metaknowledge about reading is independent of language and reading comprehension, and (d) the link between earlier mental state knowledge and later metaknowledge about reading is specific to cognitive mental state knowledge. These findings are original yet consistent with previous studies and postulated models. This is an important contribution to the existing literature, since both mental state knowledge and metacognitive knowledge are crucial for children's cognitive and social development. Finally, we believe these findings have implications for intervention and could therefore contribute to promoting efforts to connect metacognition and knowledge of mental states in an educational perspective (Gonida & Kiosseoglou, 2006).

Appendix

Example items from the Metacomprehension Questionnaire (Pazzaglia et al., 1994)

Subtest of Reading Goals

In your opinion, when you read, the most important thing is:

A. To read loudly and clearly
B. To read exactly and without hesitation every word
C. To understand the content of the text
D. To read as quickly as possible

Subtest of Reading Strategies

If you don't understand a word inside a text, You can:
A. Try to guess
B. Skip or substitute it with an other word
C. Use the rest of the sentence to understand it

Subtest of Text Sensitivity

Once upon a time there was a prince that woke a princess with a kiss. They lived happily together. This text is: ___________ ___________________________________

Example items from the Questionnaire of Metacognition (Friso et al., 2006)

If you need to remember a lesson/passage it is better:
A. To read it several times
B. To underline with a red pen
C. To remember with your words what happened
D. To study with a TV on in order to keep yourself awake

When you write, the most important thing is:
A. Make the others understand you
B. Not make spelling mistakes
C. Use unusual words
D. Write a text as long as possible

Story Task

Story 1: Luca carries out a school test and tells his mum that he has done it well. The next day he goes to school and the teacher tells him that the test is inadequate. You continue:

Story 2: Alice has been invited to Marta's birthday party and she promised she would go. When she tells her mum at home about the party, her mum reminds her that her cousin was also expecting her at another party. You continue:

Coding Categories for Mental State Words (including verbs, nouns, adverbs and adjectives) and Examples from Children's Transcripts

Cognitive words: ''She forgot to study''; ''The teacher understood that it was not true.''

Emotion words for positive and negative sensations, emotions, feelings, and emotional expressions: ''Mum was happy for the good mark and gave him a present''; ''His heart was full of satisfaction.''

Desire words for feelings of intention, desire, and possibility: ''I wish that you had informed me first''; ''He decided to continue.''

Morality words for moral feelings, emotions, opinion: ''He felt a little bit guilty''; ''He regretted doing this.''

Components of the Test of Emotion Comprehension (Pons et al., 2004)

I. Recognition: the ability to recognize and name emotions on the basis of expressive cues.
II. External Cause: the ability to understand how external causes affect the emotions of other children.
III. Desire: the ability to understand that emotional reactions of other people depend on their desires.
IV. Belief: the ability to understand that person's beliefs determine his emotions.
V. Reminder: the ability to understand that elements of a situation can reactivate past emotions.
VI. Regulation: the ability to understand strategies for emotional control.
VII. Hiding: the ability to understand the discrepancy between the expression of emotion and felt emotion.
VIII. Mixed: the ability to understand that a person may have multiple emotional responses to a given situation.
IX. Morality: the ability to understand that negative feelings ensue from a morally reprehensible action.

Example items from the Strange Stories Task (Happè, 1994)

Katie and Emma are playing in the house. Emma picks up a banana from the fruit bowl and holds it up to her ear. She says to Katie, ''Look! This banana is a telephone.''

Mental State or Justification Question: Why does Emma say this?

Examples responses scored 2: ''She's just pretending.''

Examples responses scored 1: ''Because the banana looks like a telephone.''

Holistic Face Processing in Newborns, 3-Month-Old Infants, and Adults: Evidence From the Composite Face Effect

Chiara Turati
Università degli Studi di Milano-Bicocca

Elisa Di Giorgio, Lara Bardi, and Francesca Simion
Università degli Studi di Padova

Holistic face processing was investigated in newborns, 3-month-old infants, and adults through a modified version of the composite face paradigm and the recording of eye movements. After familiarization to the top portion of a face, participants ($N = 70$) were shown 2 aligned or misaligned faces, 1 of which comprised the familiar top part. In the aligned condition, no visual preference was found at any group age. In the misaligned condition, 3-month-olds preferred the face stimulus with the familiar top part, adults preferred the face stimulus with the novel one, and newborns did not manifest any visual preference. Results revealed that both infants' and adults' eye movements may be affected by holistic face information and demonstrated holistic face processing in 3-month-olds.

The human face provides us with critical information about the age, gender, emotional state, intention, and identity of others, thus being one of the most significant visual objects a person encounters. Our ability to recognize faces at a glance requires differentiating subtle information that distinguishes each individual and concerns the shape of facial features (*featural* information), the spacing among features (*second-order configural* information), and the overall structure of the face, where face parts and their relations are glued together in an undifferentiated unit (*holistic* information; Maurer, Le Grand, & Mondloch, 2002; Tanaka & Farah, 1993). It is generally accepted that the exceptionally proficient face recognition abilities seen in adults are mainly derived from the rapid and efficient encoding of configural information, which includes sensitivity to first-order relations that specifies the stimulus as a face, holistic processing that interconnects facial features in a single unit, and sensitivity to second-order relations that defines differences among individuals in the spacing of facial features (Maurer et al., 2002). The current article focused on holistic processing, investigating through the testing of the composite face illusion newborns' and 3-month-old infants' sensitivity to holistic face information.

Although experience-based developmental processes progressively refine early configural face recognition abilities, available evidence demonstrates that configural processing emerges during the first months of life rather than undergoing a long developmental trajectory. At birth, sensitivity to *first-order* configural information is demonstrated by newborns' preference for faces as compared to equally complex nonface visual stimuli (Johnson & Morton, 1991; Valenza, Simion, Macchi Cassia, & Umiltà, 1996). By the age of 4 months, infants can discriminate faces on the basis of *second-order* configural changes in the spatial relations between facial features (Bhatt, Bertin, Hayden, & Reed, 2005; Deruelle & de Schonen, 1998; Hayden, Bhatt, Reed, Corbly, & Jospeh, 2007; Thompson, Madrid, Westbrook, & Johnston, 2001). Moreover, newborns' and 4-month-old infants' ability to recognize faces is deteriorated by face inversion, suggesting a reliance on configural information in processing upright faces (Turati, Macchi Cassia, Simion, & Leo, 2006; Turati, Sangrigoli, Ruel, & de Schonen, 2004).

Research was supported by grants from Ministero dell'Università (2007XFM93B_004) and University of Padua (2007-CPDA 075245). We thank Dr. Dalla Barba and the nursing staff at the Pediatric Clinic for their collaboration. Many thanks also to Dr. Bruno Rossion and Dr. Adelaide de Heering for sharing the composite face stimuli, and Jennifer Wagner for English editing.

Finally, 6-month-olds and newborns can discriminate upright Thatcher faces (eyes and mouth reversed on the face) from non-Thatcher faces, even though only relational aspects of the features—second-order configural information—differentiate the two stimuli (Bertin & Bhatt, 2004; Leo & Simion, 2009).

Infants' processing of *holistic* face information has received far less attention with few studies examining infants' ability to process the multiple features of a face as a perceptual unit. The only available evidence showed that 4-month-olds look longer at a "switched" face made up of the internal features of a familiar face and the external features of a different familiar face than at each whole familiar face, indicating that they process the configuration made up of internal and external features (Cashon & Cohen, 2001, 2003). Nevertheless, such studies focused exclusively on the correlations between outer and inner face features. Yet, the inner part of the face per se contains sufficient cues to support 4-month-old infants' face recognition. Newborns use information about internal facial features in making preferences based on attractiveness (Slater et al., 2000) and are able to recognize a face based solely on its inner face part (Turati et al., 2006). Thirty-five- to 40-day-old infants are able to discriminate their mother from a stranger even when the whole line between face and hair is masked by a scarf, thus relying mostly on the inner portion of the face (Bartrip, Morton, & de Schonen, 2001). Following familiarization to unfamiliar faces, similar results have been obtained at 1, 3, and 6 months of age (de Haan, Johnson, Maurer, & Perrett, 2001; Pascalis, de Haan, Nelson, & de Schonen, 1998). Nevertheless, holistic processing of internal features per se, rather than in relation with outer features, has never been tested in infants.

Also, the "switch" paradigm used with infants highly differs from the paradigms commonly employed to test holistic face processing abilities in older children and adults, specifically the part–whole paradigm and the composite paradigm. In the part–whole paradigm, recognition of a face part is measured when presented in the context of the whole face relative to when presented in isolation, and better performance is typically observed for the whole compared to the part condition (Tanaka & Farah, 1993). Pellicano and Rhodes (2003) provided evidence that 4-year-olds manifest a part–whole effect, indicating that they recognize faces holistically. The composite effect is commonly taken as the most compelling evidence that facial features are integrated into a holistic representation of an individual face by human observers and refers to the observation that recognition of the top half of a face is more difficult when the top half is aligned with the bottom half of a different face, creating the impression of a novel face, as compared to when the two halves are misaligned through a lateral shift (Hole, 1994; Young, Hellawell, & Hay, 1987). The difference between the subjects' performance in the aligned and misaligned condition is taken as a measure of the interference produced by holistic processing of the novel composite face on the recognition of its constituent parts. The composite effect has been demonstrated at 6 years of age for both familiar (Carey & Diamond, 1994) and unfamiliar (Mondloch, Pathman, Maurer, Le Grand, & de Schonen, 2007) faces, and recently in preschool-aged children (de Heering, Houthuys, & Rossion, 2007; Macchi Cassia, Picozzi, Kuefner, Bricolo, & Turati, 2009).

This study addressed holistic face processing in 3-month-old infants (Experiment 1), newborns (Experiment 2), and adults (Experiment 3) through the use of a modified version of the composite face task and the recording of eye movements. The classical composite face paradigm used with adults and preschool- or school-age children was modified in order to be adapted to infants, who are unable to comprehend written or verbal instructions and to provide a manual response. The same paradigm was applied also to adult participants (Experiment 3), because, despite the rich literature on the composite effect in adults, only a single study recorded adults' eye movements during the composite task (de Heering, Rossion, Turati, & Simion, 2008). Thus, Experiment 3 tested whether gaze behavior in adults is affected by the use of holistic face-processing strategies in a composite paradigm analogous to that employed with infants. Newborns, 3-month-old infants, and adults were tested using a visual paired-comparison task (VPC). Eye movements (duration and number of fixations) toward the top and bottom halves of the composite faces were recorded in 3-month-olds (Experiment 1) and adults (Experiment 3) using an eye-tracker system. Newborns were tested through a classical habituation paradigm in which the duration of visual fixations is coded by human expert observers. During the habituation-familiarization phase, all participants were presented with a top half of a face. The test phase involved the presentation of a pair of composite face stimuli. In one face stimulus of the pair, the top half of the face was identical to the one shown during familiarization, and the top of the other face was new.

Half of the participants were tested in the aligned condition, in which the left and right margins of the top and bottom face parts were properly aligned, and the other half were tested in the misaligned condition, in which the top and bottom face parts were offset horizontally.

Experiment 1

Method

Participants. Participants were twenty 3-month-old healthy and full-term infants (13 males, mean age = 99 days). They were middle-class infants and all of them except one were Caucasian. Seven additional infants were tested but not included in the final sample because they showed a strong position preference (i.e., they looked to one direction more than 90% of the time). Infants were tested only if awake and in an alert state after parents gave their informed consent.

Stimuli. The original stimuli were digitized, high-quality gray-scale images of 12 Caucasian female full-front faces, posing with a neutral expression and placed on a black background with no hair. All faces were unfamiliar to participants. Face images were split into two parts at the level of the middle of the nose, generating a top and a bottom segment. Composite faces were created by joining the top segment of one face to the bottom segment of a different face image (Young et al., 1987; Figure 1). By that matching, six pairs of faces were created. Within each pair, the bottom face half was the same. In the *aligned condition*, the top and the bottom face segments were properly horizontally aligned, whereas in the *misaligned condition* the top half of each face was shifted horizontally to the left, so that the middle of the nose in the bottom segment was positioned next to the extreme right side of the top segment. In both conditions, the two halves of each composite face were separated by a gap of 3 mm. When projected onto the screen, the top part presented in the habituation phase was 8 × 12 cm (about 8° × 11° of visual angle). Aligned faces were 15.5 × 12 cm (about 15° × 11° of visual angle). Misaligned faces were 15.5 × 17.5 cm (about 15° × 17° of visual angle). The distance between the center of the screen and the vertical median line of each stimulus was about 13.5 cm (about 13° of visual angle).

Apparatus. Infants were placed in an infant seat at a distance of about 60 cm from the computer screen where the stimuli were presented. A system for the automatic registration of eye movements made by Applied Science Laboratories (ASL) was employed and consisted of an infrared camera located at the bottom of the computer screen. Using a remote control and a live image of the participant's left eye, an experimenter, blind to the purpose of the study, guided the camera to keep the participant's eye constantly in focus. The eye-tracking system automatically detected the position of the pupil and the corneal reflection of the infrared light-emitting diodes (LEDs) in the eye. Because these signals changed as a function of the observer's gaze direction, the apparatus determined, with a frequency of 50 Hz, the x–y coordinates corresponding to the participant's fixation points during stimulus presentation. Two crosses of different colors corresponding to the signals coming from the participant's pupil and corneal reflection were superimposed on the images of the stimuli presented, giving a second experimenter a direct indication of the quality of the signal collected during the experiment. Stimulus presentation and data collection were performed using E-Prime 1.1. (Psychological Software Tool, Pittsburgh, PA).

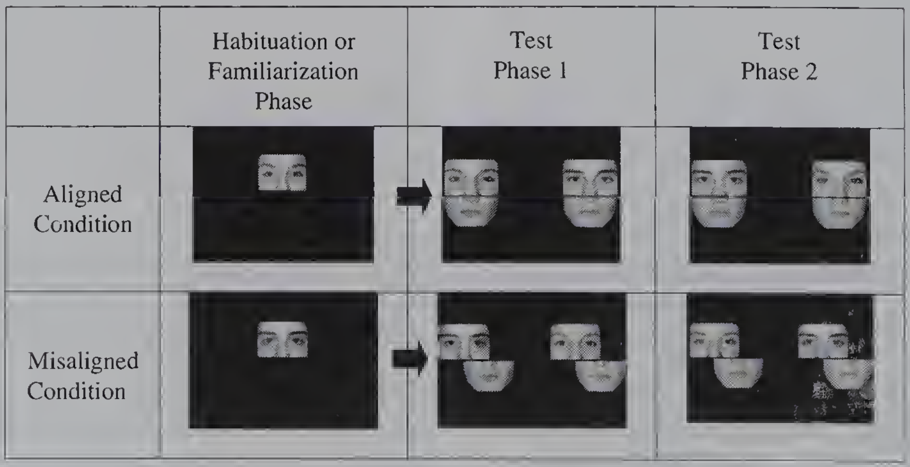

Figure 1. The stimuli and procedure used in Experiments 1–3.

Procedure. Each infant was tested on a single occasion in a quiet and dark room, seated approximately 60 cm from a 19-in. (1,024 × 768 pixels) computer screen. The experiment started with a calibration phase immediately followed by the habituation phase and the test phase. During calibration, a smiley face cartoon was presented in the center of the screen. When the infant started to look at it, the smiley moved to the top left corner of the screen and remained in this position until the infant fixated it. Then, it moved to the bottom right corner and remained in this position. These three positions were used to compute the pupil-corneal reflection from three points on the screen, allowing the system to derive gaze direction during the habituation and the test phases. Calibration accuracy was checked and repeated if necessary.

An infant-control habituation paradigm (Slater, Morison, & Rose, 1985) was used. Applying the ASL algorithm, a fixation was defined as a period of a least 100 ms during which the fixation point did not change by more than 1° of visual angle. During the habituation phase, the top half portion of a face was presented at the center of the screen. The infant was judged to have habituated when, from the fourth fixation on, the sum of any three consecutive fixations was 50% or less than the total of the first three. In the test phase, each infant was given two paired presentations of the test stimuli, in which the left–right stimulus position was reversed. In one face of the pair the top half was identical to that shown during habituation, in the other face the top half was new. Both top halves were matched with the same bottom half of a third new face. Each presentation lasted when a total of 10 s of looking at the novel and/or familiar stimuli had been accumulated. Half of the infants were tested in the aligned condition, the other half were tested in the misaligned condition.

Number of fixations and total fixation times were calculated by computing the sum of all fixations within four areas of interest (AOI) of the composite faces presented in the test phase (AOIs, Figure 2), which corresponded to the face halves that appeared on the left and right sides of the screen: AOI 1 and AOI 2 for the top halves of faces presented, respectively, on the left and on the right of the screen; AOI 3 and AOI 4 for the bottom halves of faces presented on the left and on the right of the screen.

Results

All infants reached the habituation criterion. A paired-sample t test was run to compare total fixation times to reach the habituation criterion in each condition, aligned condition ($M = 27{,}180$ ms, $SE = 5{,}755$) versus misaligned condition ($M = 19{,}618$ ms, $SE = 3{,}553$), $t(18) = 1.12$, *ns*. The difference was not significant.

To understand if infants' gaze behavior differed depending on the alignment versus misalignment of the top and bottom face portions, total looking times and number of fixations toward the top and bottom parts of the faces in the test phase were analyzed. The face that comprised the top half presented in the habituation phase was considered as familiar whereas the other was considered as novel. Preliminary analyses of variance (ANOVAs) on number of fixations and total fixation times toward the stimuli revealed that no main effect or interactions involved the factor presentation (first vs. second). Therefore, data were collapsed across this factor in two distinct three-way ANOVAs, performed on total fixation times and number of fixations, with test (novel vs. familiar) and face half (top vs. bottom) as within-subjects factors and testing condition (aligned vs. misaligned) as between-subjects factor.

Results of the ANOVA on total fixation times showed a main effect of the face half factor, $F(1, 18) = 82.53$, $p < .001$, $\eta^2 = .82$. Infants looked longer at the top face part ($M = 3{,}382$ ms, $SE = 206$) than at the bottom face part ($M = 720$ ms, $SE = 159$).

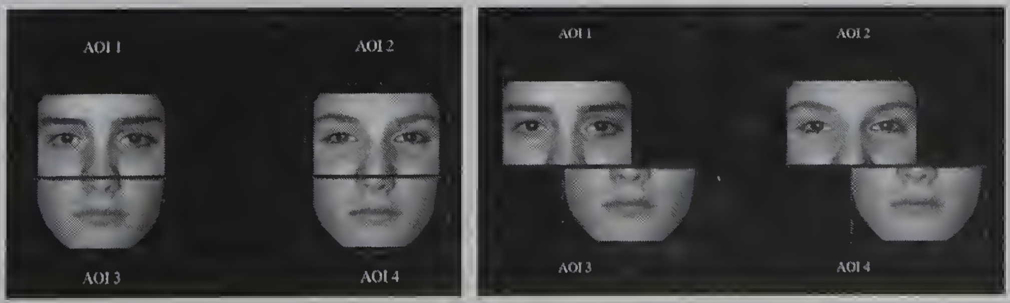

Figure 2. Areas of interest (AOIs) used in Experiments 2 and 3.

Furthermore, the main effect of test indicated that the familiar face (M = 2,322 ms, SE = 196) was fixated longer than the novel face (M = 1,780 ms, SE = 110), $F(1, 18) = 5.72$, $p < .05$, $\eta^2 = .24$. This test main effect could be explained in relation to the Test × Testing Condition significant interaction, $F(1, 18) = 4.56$, $p < .05$, $\eta^2 = .20$, which qualifies the main effect (Figure 3). Indeed, planned t tests showed that, in the misaligned test condition, infants looked longer at the familiar (M = 5,326 ms, SE = 645) than at the novel (M = 3,273 ms, SE = 366) composite stimulus, $t(9) = 2.66$, $p < .05$. On the contrary, in the aligned test condition, looking time toward the novel (M = 3,847 ms, SE = 244) and the familiar (M = 3,963 ms, SE = 446) faces did not differ, $t(9) = 0.24$, *ns*.

Results of the ANOVA on number of fixations showed a main effect of face half, $F(1, 18) = 88.59$, $p < .001$, $\eta^2 = .83$, and a significant Face Half × Testing Condition interaction, $F(1, 18) = 4.55$, $p < .05$, $\eta^2 = .20$, showing that the number of fixations infants oriented to the top face part (M = 40, SE = 2) was greater than the number of fixations toward the bottom face part (M = 11 ms, SE = 1), particularly in the misaligned (M = 44, SE = 3 vs. M = 9, SE = 3) as compared to the aligned test condition (M = 35, SE = 1 vs. M = 13, SE = 2).

Discussion

In accordance with previous evidence (Gallay, Baudouin, Durand, Lemoine, & Lécuyer, 2006; Turati, Valenza, Leo, & Simion, 2005), our findings showed that in both the aligned and the misaligned conditions, infants' visual exploration was focused on the top portion of the face, that comprised the eye region. More interestingly, results revealed a discrepancy in infants' looking times according to the alignment or misalignment of the faces. Three-month-olds looked longer at the face with a familiar top half when the top and the bottom face halves were misaligned, thus revealing that they discriminated the two stimuli. Conversely, in the aligned condition infants looked equally long to the familiar and novel stimuli, indicating that they did not differentiate between the two. This suggests that the bottom part of the composite faces affected infants' performance in both the aligned and the misaligned conditions. In the aligned condition, the novel bottom face halves impaired infants' discrimination of the two composite faces. In the misaligned condition, the addition of the bottom face half determined a persistent and extensive reexploration of the familiar top face half. Indeed, previous studies that tested infants' ability to recognize a learned face over strong modifications—such as partial occlusion, or rotation—obtained a familiarity preference (Gava, Valenza, Turati, & de Schonen, 2008; Walton, Amstrong, & Bower, 1997; see also Sirios & Mareschal, 2002, 2004). In the current experiment, infants in the misaligned condition not only recognized the familiarity of the top portion of the configuration but also detected that a novel never-seen bottom face part was added to the familiar part. This induced infants' extensive reexploration of the whole partially familiar stimulus.

The alignment versus misalignment of faces also affected the trajectories of infants' eye movements, as infants' tendency to fixate the top versus the bottom face halves was more evident in the misaligned condition, that is when the top part of the faces are disjoined from the bottom parts. Thus, overall, evidence obtained through the use of an eye-movement recording VPC procedure supports the existence of the composite effect in 3-month-old infants.

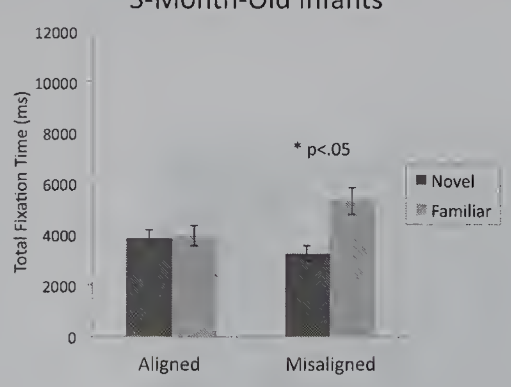

Figure 3. Total fixation time at the novel and the familiar stimuli as a function of test condition (aligned vs. misaligned condition) in Experiment 1.

Experiment 2

Method

Participants. Participants were 28 (14 females) healthy, full-term newborns (mean age = 45 hr), recruited at the maternity ward of the Pediatric Clinic of the University of Padova. All of them were middle-class infants and Caucasian. Nine additional newborns were tested but were not included in the final sample because 1 showed a strong position preference (i.e., he looked to one direction more than 80% of the time) and 8 did not complete testing due to fussiness. All of them met the screening criteria of normal delivery, a birth weight between 2,460 and 4,100 g, and an Apgar score between 8 and 10 at 5 min. Newborns were tested only if they were awake and in an alert state, after parents gave their informed consent.

Stimuli. The stimuli were identical to those presented in Experiment 1, except for dimensions expressed in visual angles that changed as 3-month-old infants were placed at a greater distance (60 cm) from the screen than newborns (30 cm). When projected on the screen, the two top parts presented in the habituation phase were 8 × 12 cm (about 15° × 23° of visual angle). Aligned faces were 15.5 × 12 cm (about 27° × 23°). Misaligned faces were 15.5 × 17.5 cm (about 27° × 33°). The distance between the center of the screen and the vertical median line of each figure was about 13.5 cm (about 26°).

Apparatus. The infant sat on the experimenter's lap, 30 cm from a 30-in. computer screen (2,560 × 1,600). Infants' eyes were aligned with a red flickering LED at the center of the screen, which was used to attract the infant's gaze at the start of each trial and to check that the infant's sight was level with the horizontal midline of the screen during the testing session. Stimuli were projected bilaterally on a black screen at a distance of approximately 7.5 cm (15°) from a central fixation point. A video camera, mounted above the central screen, recorded the infant's eyes movements. To prevent interference from irrelevant distracters, plain white curtains were drawn on both sides of the chair where the experimenter sat with the baby in her lap.

Procedure. Testing began as soon as the newborn looked at the central flickering LED. The experiment was carried out using an infant-control habituation procedure (Horowitz, Paden, Bhana, & Self, 1972). At present, the eye-tracker system is inappropriate for use with newborns because of the poor differentiation of the pupil at birth, which renders almost impossible for the infrared camera to detect the position of the pupil and the corneal reflection of the infrared LEDs in the newborns' eye. An experimenter, who was naïve to the hypotheses under investigation, watched the infants' eyes by means of a video monitor system and coded the duration of newborns' fixations toward the novel or the familiar composite face by pressing a key on the computer keyboard. During the habituation phase, newborns were presented with two top halves of the same face presented bilaterally. Bilateral rather than central presentation was chosen because it is difficult for an observer to decide if newborns are actually looking at a centrally presented stimulus or if they simply do not move their eyes from the central position. Also, at birth photoreceptors in the central fovea are very immature, thus resulting in a poor vision in the central area of visual field (Abramov et al., 1982; Atkinson & Braddick, 1989).

The stimuli remained on the screen until the habituation criterion was established through the recording of the duration of individual fixations. The duration of each fixation on the stimulus was recorded by pressing a button that was connected to the computer. During the habituation phase, the same stimulus was presented on the left and on the right, so the amount of looking was recorded irrespective of the side. The habituation criterion was identical to the one used in Experiment 1. When the habituation criterion was reached, the stimuli were automatically turned off and the central flickering LED was turned on. When the infants' gaze was realigned to the central LED, a preference test phase started. Each infant was given two paired presentations of the stimuli. During each presentation, newborns were simultaneously presented with a pair of composite faces. In one face of the pair, the top half was identical to that shown during habituation, in the other face the top half was new. Both top halves were matched with the same bottom half of a third new face. The two-paired stimuli were always shown in both left and right positions, the position being reversed from Presentation 1 to Presentation 2. During the preference test phase, the experimenter recorded the duration of infant's fixations and the number of fixations on each stimulus by pressing two different push buttons depending on whether the infant looked at the right or the left position. Each presentation lasted until each stimulus had been fixated at least once and a total of 20 s of looking had been accumulated. The test presentations were kept longer in Experiment 2 (20 s of fixation time) than in Experiment 1 (10 s of fixation time) to give newborns more time to process the stimuli and eventually manifest a novelty preference. Half of the infants were tested in the aligned condition, the other half were tested in the misaligned condition.

Results

All newborns reached the habituation criterion. A paired-sample t test was run to compare total fixation times to reach the habituation criterion in each condition (aligned condition, M = 65,210 ms, SE = 10,456 vs. misaligned condition, M = 74,886 ms, *SE* = 11,220). The comparison did not reach statistical significance, *t*(27) = 1.23, *ns*.

Preliminary ANOVAs on total fixation times and number of fixations toward the stimuli revealed that no main effect or interactions involved the factor presentation (first vs. second). Therefore, data were subsequently collapsed in two ANOVAs with testing condition (aligned vs. misaligned) as between-subjects factor and test (novel vs. familiar) as within-subjects factors, one for each dependent variable. The face stimulus that comprised the top half presented in the habituation phase was considered as familiar. There was no main effect, *F*(1, 26) = 0.45, *ns*, or interactions involving the factor test, *F*(1, 26) = 0.99, *ns* (Figure 4). Results showed that newborns looked equally long at the novel stimulus as compared to the familiar stimulus in the both the aligned (*M* = 22,248 ms, *SE* = 5,458 vs. *M* = 22,494 ms, *SE* = 8,131) and misaligned (*M* = 20,542 ms, *SE* = 5,834 vs. *M* = 20,733 ms, *SE* = 7,745) conditions. Furthermore, analyses with total number of fixations showed no main effect of the factor test, *F*(1, 26) = 0.13, *ns*, nor an interaction between the factors test and testing condition, *F*(1, 26) = 1.85, *ns*.

Discussion

The results of Experiment 2 showed that neither newborns tested in the aligned condition nor newborns tested in the misaligned condition discriminated the familiar from the novel composite face. Different possible explanations of the obtained results might be provided. One possibility is that newborns based their response in the test phase on the bottom half of the composite faces, which was identical in both the stimuli that comprised the novel and the familiar top halves. This explanation is not plausible given that less salient and contrasted areas are embedded in the bottom as compared with the top face part (Gava et al., 2008; Turati, 2004). Alternatively, newborns may have reacted to the significant perceptual change that occurred between the habituation phase (in which only one top half of a face was presented) and the test phase (in which two faces were presented, each comprising a novel bottom half) and showed a persistent and comparable exploration of both the familiar and the novel composite face. Finally, newborns might be unable to recognize a portion of a face—that is, only the top part rather than the full face—given that first-order face information is absent and second-order face information is poorly represented, the spatial relations between eyes and nose and eyes and mouth being disrupted. Future studies might further explore this issue by presenting newborns with a composite face rather than a top face part, in the habituation phase.

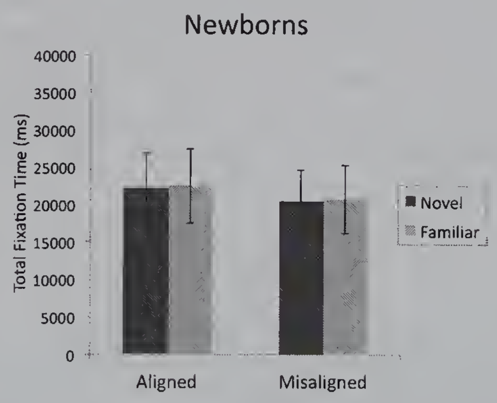

Figure 4. Total fixation time at the novel and the familiar stimuli as a function of test condition (aligned vs. misaligned condition) in Experiment 2.

Experiment 3

To ground the results obtained in Experiments 1 and 2 in an adult model, Experiment 3 tested a group of adults in a similar VPC task. In adults, the active control of eye fixations plays an important functional role in a wide variety of cognitive and perceptual tasks (for a review, see Henderson, 2006). Adults' eye fixations during face perception and recognition are predominantly directed to internal facial features, particularly the eyes, then nose and mouth (Althoff & Cohen, 1999; Henderson, Falk, Minut, Dyer, & Mahadevan, 2001; Stacey, Walker, & Underwood, 2005). Recently, a functional relation between eye movements and face perception has been demonstrated, in that a deficit in recognition emerged when participants were required to keep their eyes fixated in one central position (i.e., restricted viewing condition) rather than to move their eyes freely (i.e., free-viewing condition; Henderson, Williams, & Falk, 2005). Finally, Williams and Henderson (2007) found that the same features of a face were fixated regardless of whether the face was right side up or upside down and interpreted their findings as indicating that the face inversion effect is not the result of a different pattern of eye movements (but see Gallay et al., 2006, for qualitative differences in visual exploration strategies between upright and inverted faces in 4-month-olds).

Through the recording of adults' eye movement during a composite task, Experiment 3 was aimed at test gaze behavior during holistic face processing. Despite numerous studies on adults' composite face illusion, only a single study recorded eye movements while adults performed a delayed matching task of top halves of faces aligned or misaligned with bottom face halves (de Heering et al., 2008). Results showed that participants fixated longer the top parts of aligned than misaligned faces, suggesting the presence of a difference in eye-movement strategies between the aligned and misaligned conditions. However, manual reaction time data were strictly linked to eye-recording data, as suggested by the high correlations between participants' manual response time and ocular fixation time in aligned and misaligned conditions. When the effect of participants' manual response time was controlled, considering the variable as a covariate, the difference in mean fixation time on the top parts of aligned and misaligned faces disappeared, suggesting that longer fixation time on the top parts of aligned versus misaligned faces was due to the time devoted to respond manually at aligned versus misaligned faces, aligned faces being processed more slowly.

In light of this result, in the current experiment adults' eye movements were recorded in a free-viewing task that does not require a manual response. In parallel with the experimental paradigm used with 3-month-old and newborn infants in Experiments 1 and 2 and with studies that used the VPC task with adults (Richmond, Sowerby, Colombo, & Hayne, 2004), participants were familiarized with the top half of a face in a single fixed 15-s presentation. In the subsequent two fixed 10-s presentation test phases, a pair of composite faces was shown in which one of the face top halves was identical to the top half of the face presented during familiarization and the other top half was new. Half of the participants were tested in the aligned condition, and the other half were tested in the misaligned condition, so that alignment of the composite stimuli was varied between subject as in Experiments 1 and 2. No instructions were given, except that participants had to watch the images appearing on the computer screen moving their eyes freely.

Method

Participants. The participants were 22 undergraduate middle-class, Caucasian students (17 females, $M = 22.8$ years) from the Department of Psychology at the University of Padua (Italy). Seven additional participants were tested but excluded from the final sample due to failure to reach criteria established for data analyses (their fixation time toward stimuli was less than 70% of the total presentation time during both first and second test phases). All of them had normal or corrected to normal vision.

Stimuli. The stimuli were identical to those used in Experiments 1 and 2.

Apparatus and procedure. The apparatus and the procedure were the same as with 3-month-old infants in the previous experiment, with one exception. Following the calibration phase, instead of the habituation phase, participants were familiarized with a top half of a face projected in the center of the screen for a fixed presentation period of 15 s. Half of the participants were tested in the aligned condition, whereas the other half in the misaligned condition. Participants were given no instructions except that they had to watch the images appearing on the screen.

Results

To compare total fixation times in the aligned and misaligned conditions during the familiarization phase, a paired-sample t test was run (aligned condition, $M = 11{,}773$ ms, $SE = 762$ vs. misaligned condition, $M = 12{,}709$ ms, $SE = 434$), $t(20) = 1.06$, *ns*. As expected, the difference was not significant.

As with infants in Experiment 1, the aims of the statistical analyses performed on the data were to understand (a) whether adults' ability to discriminate the familiar from the novel composite face varied as a function of the alignment or misalignment of the face halves, and (b) whether the pattern of adults' fixation durations to the top and bottom halves of the composite faces varied between the two alignment conditions.

The face stimulus that comprised the top half presented in the habituation phase was considered familiar whereas the other was considered novel. Two distinct mixed-model ANOVAs were performed on total fixation times and number of fixations with presentation (first vs. second), test (novel vs. familiar), and face half (top vs. bottom) as within-subjects factors and testing condition (aligned vs. misaligned) as between-subject factor.

Results of the ANOVA on total fixation times showed that adults looked longer at the top face halves ($M = 2{,}869$ ms, $SE = 121$) than at the bottom face halves ($M = 1{,}062$ ms, $SE = 107$) as showed by the main effect of face half, $F(1, 20) = 65.33$, $p < .001$, $\eta^2 = .76$. More importantly, there was a significant interaction between the factors test and testing condition, $F(1, 20) = 6.51$, $p < .05$, $\eta^2 = .24$ (Figure 5). Planned *t* tests showed that in the misaligned test condition, adults looked longer at the novel stimulus ($M = 9{,}107$ ms, $SE = 516$) than at the familiar stimulus ($M = 6{,}762$ ms, $SE = 498$), $t(10) = 2.41$, $p < .05$. On the contrary, in the aligned test condition, mean fixation time toward the novel face ($M = 7{,}229$ ms, $SE = 435$) and the familiar face ($M = 8{,}356$ ms, $SE = 539$) did not differ, $t(10) = 1.19$, *ns*. This suggests that, in the aligned condition, the bottom part of the composite faces affected adults' performance, impairing their face recognition ability.

Finally, the interaction between the factors presentation and test also reached statistical significance, $F(1, 20) = 9.55$, $p < .05$, $\eta^2 = .32$. Specifically, planned *t* tests showed that adults looked longer at the novel stimulus ($M = 4{,}556$ ms, $SE = 257$) than at the familiar one ($M = 3{,}320$ ms, $SE = 243$) during the first test phase, $t(21) = 2.52$, $p < .05$, whereas there were not differences in looking behavior toward novel ($M = 3{,}612$ ms, $SE = 231$) and familiar ($M = 4{,}239$ ms, $SE = 285$) stimulus in the second test phase, $t(21) = 1.24$, *ns*.

The ANOVA on number of fixations revealed no main effect or interactions involving the factor Presentation (first vs. second). Therefore, data were collapsed across this factor in a subsequent three-way ANOVA with test (novel vs. familiar) and face half (top vs. bottom) as within-subjects factors and testing condition (aligned vs. misaligned) as between-subjects factor.

Results indicated a main effect of face half, $F(1, 20) = 90.34$, $p < .001$, $\eta^2 = .82$. The number of fixations adults made to the top part of the face ($M = 36$, $SE = 2$) was greater than the number of fixations toward the bottom part of the face ($M = 13$, $SE = 1$). Furthermore, the significant interaction between face half and testing condition, $F(1, 20) = 5.38$, $p < .05$, $\eta^2 = .21$, showed that the difference between fixations to the top part of the face and the bottom part of the face was greater in the aligned test condition ($M = 39$, $SE = 2$ vs. $M = 10$, $SE = 1$) than in the misaligned test condition ($M = 34$, $SE = 2$ vs. $M = 17$, $SE = 3$). Furthermore, there was a significant interaction between the factors test and testing condition, $F(1, 20) = 6.23$, $p < .05$, $\eta^2 = .24$. Planned *t* tests showed that, in the misaligned test condition, the number of fixations toward the novel stimulus ($M = 29$, $SE = 2$) was greater than the number of fixations toward the familiar stimulus ($M = 22$, $SE = 2$), $t(10) = 2.97$, $p < .05$. On the contrary, in the aligned test condition, the number of fixations toward the novel ($M = 24$, $SE = 2$) and the familiar faces ($M = 25$, $SE = 1$) did not differ, $t(10) = 0.61$, *ns*.

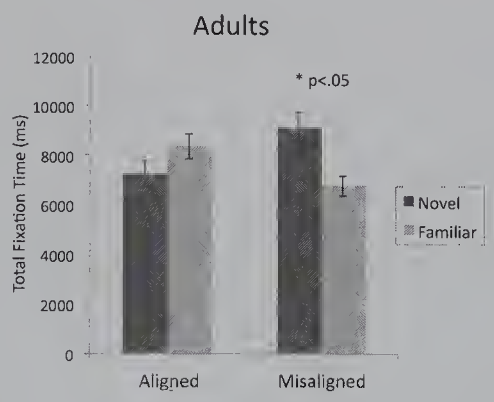

Figure 5. Total fixation time at the novel and the familiar stimuli as a function of test condition (aligned vs. misaligned condition) in Experiment 3.

Discussion

Evidence from the present experiment appears in line with previous findings showing that adults' fixations toward faces are directed predominantly toward the eye regions (e.g., Althoff & Cohen, 1999; Henderson et al., 2001; Henderson et al., 2005). Importantly, adults looked longer and directed a greater number of fixations toward the face with a novel top half in the misaligned condition. Conversely, in the aligned condition adults looked equally long and oriented their gaze approximately the same number of times toward the novel and familiar stimuli. This suggests that, in the aligned condition, the bottom part of the composite faces affected adults' performance, demonstrating the presence of the composite face effect. Aligned versus misaligned stimulus conditions elicited differential looking times and numbers of fixations for the novel and the familiar composite face, providing evidence that eye movements may be affected by the encoding of holistic face information.

Overall, the present work is consistent with the idea that eye movements during face recognition are functional (Henderson et al., 2005) but is partially in contrast with the findings reported by de Heering et al. (2008) on the composite effect and by Williams and Henderson (2007) on the inversion effect, according to which eye-movement patterns are not able to reflect holistic processing strategies. The discrepancies between our studies and previous work may be explained by at least three major methodological differences. First, in our study participants were not required to provide a manual response. This may have avoided high correlations between participants' manual response time and ocular fixation time that could produce distortions in the results related to eye movements, as longer manual reaction times are associated with longer fixations. Second, with respect to the study by de Heering et al., participants were not explicitly required to look at the top part of a face in order to recognize it but were allowed to freely move their eyes. In accord with de Heering et al., we found that the top halves of the composite faces in the test phase were fixated longer than the bottom halves, irrespective of whether the face halves were aligned or misaligned. However, different from de Heering et al., in our study the aligned and misaligned conditions affected the amount of visual exploration of the novel and the familiar composite faces and number of fixations directed toward the top and the bottom composite face part. Third, differently from the study by Williams and Henderson, the use of the composite paradigm allowed us to split faces into only two critical AOI (top face part and bottom face part) rather than in multiple areas related to each face feature (left eye, right eye, nose, mouth, chin, forehead, etc.). This might have produced a more adequate measure of holistic, rather than feature-based, face processing strategies.

General Discussion

The main outcome of this study is that for the first time a clear demonstration was provided that young infants are capable of processing a face holistically, as an undifferentiated unit in which face parts and their relations are glued together (Experiment 2). The present work extends previous findings that reported a measure of the composite effect at 3 years of age (Macchi Cassia et al., 2009) and of the part–whole effect at 4 years of age (Pellicano & Rhodes, 2003). Also, the present results extend previous findings obtained by Cohen and colleagues, demonstrating that infants are capable of detecting correlations not only between outer and inner face features (Cashon & Cohen, 2001, 2003) but also between the sole inner features of a face.

Importantly, this study utilized a version of the composite paradigm adapted to infants but comparable to the measures employed to examine holistic processing in older children and adults. In fact, this paradigm was shown to be a potential measure of the composite face effect also in adults (Experiment 3), demonstrating that eye movements (duration and number of fixations) may be sensitive to holistic face processing during the entire life span. The use of the same task throughout development, from early infancy to adulthood, allows researchers to highlight both differences and similarities in the visual behavior across age groups. First, results clearly show that the facial features that attract both adults' and infants' ocular fixations are almost the same, in that at both ages a clear tendency to explore the top rather than the bottom face part was found. Second, although both age groups visually recognized the familiar stimulus in the misaligned but not in the aligned condition, infants preferred looking at the face with the familiar top part whereas adults tended to look longer at the face with the novel top part. Thus, adults did not need to reexplore the stimulus that comprises the familiar top of the face and directly focused attention on the face stimulus with a novel top. Overall, evidence from this study reveals that the tuning toward configural information appears very early in life, although gradual experience-based developmental processes will progressively refine early configural abilities.

Child Development, November/December 2010, Volume 81, Number 6, Pages 1906–1910

Manuscripts Accepted for Publication

An Ecological Approach to Promoting Early Adolescent Mental Health and Social Adaptation: Family Centered Intervention in Public Middle Schools, Elizabeth Stormshak, Arin M. Connell, Marie-Helene Veronneau, Michael W. Myers, Thomas J. Dishion, Kathryn Kavanagh, and Allison S. Caruthers.

Assessing the Effects of a Work-Based Antipoverty Program for Parents on Youth's Future Orientation and Employment Experiences, Rachel Kaplan, Vonnie C. McLoyd, Kelly Purtell, and Aletha Huston.

Adolescents' Development of Skills for Agency in Youth Programs: Learning to Think Strategically, Reed Larson and Rachel Angus.

Intergenerational Continuity in Child Maltreatment: Mediating Mechanisms and Implications for Prevention, Lisa Berlin, Karen Appleyard, and Kenneth Dodge.

Two-Year-Olds Use the Generic/Non-Generic Distinction to Guide Their Inferences About Novel Kinds, Susan Graham, Samantha Nayer, and Susan Gelman.

Understanding Bullying and Victimization During Childhood and Adolescence: A Mixed Methods Study, Nancy Guerra, Kirk R. Williams, and Shelly Sadek.

A Large-Scale Evaluation of the KiVa Anti-Bullying Program, Antti Kärnä, Marinus Voeten, Elisa Poskiparta, Todd D. Little, Anne Kaljonen, and Christina Salmivalli.

Danish Majority Children's Reasoning About Exclusion Based on Gender and Ethnicity, Signe Juhl Moller and Harriet Tenenbaum.

How Does It Look? Level 2 Perspective-Taking at 36 Months of Age, Henrike Moll and Andrew Meltzoff.

Emotion Discourse, Social Cognition, and Social Skills in Children With and Without Developmental Delays, Rachel M. Fenning, Bruce L. Baker, and Jaana Juvonen.

A Monozygotic Twin Differences Study of Friends' Aggression and Children's Adjustment Problems, Frank Vitaro, Mara Brendgen, Michel Boivin, Stephane Cantin, Ginette Dionne, Richard E. Tremblay, Alain Girard, and Daniel Perusse.

Gender Differences in Adolescents' Daily Interpersonal Events and Well-Being, Lisa Flook.

Teacher–Child Relationships and the Development of Academic and Behavioral Skills During Elementary School: A Within- and Between-Child Analysis, Carolina Maldonado-Carreño and Elizabeth Votruba-Drzal.

The Effects of the Fast Track Preventive Intervention on the Development of Conduct Disorder Across Childhood, Conduct Problems Prevention Research group.

Object Similarity Bootstraps Young Children to Action-Based Verb Extensions, Etsuko Haryu, Mutsumi Imai, and Hiroyuki Okada.

The Impact of Enhancing Students' Social and Emotional Learning: A Meta-Analysis of School-Based Universal Interventions, Joseph Durlak, Roger Weissberg, Allison Dymnicki, Rebecca Taylor, and Kriston Schellinger.

Science Does Not Speak for Itself: Translating Child Development Research for the Public and its Policymakers, Jack Shonkoff and Susan Nall Bales.

Domain General Constraints on Statistical Learning, Erik Thiessen.

Reciprocal Relations Between Parenting and Adjustment in a Sample of Juvenile Offenders, Lela Rankin Williams and Laurence Steinberg.

A Randomized Controlled Trial of Child FIRST: A Comprehensive Home-Based Intervention Translating Research Into Early Childhood Practice, Darcy I. Lowell, Alice S. Carter, Leandra Godoy, Belinda Paulicin, and Margaret J. Briggs-Gowan.

Latino Adolescents' Experiences of Discrimination Across the First Two Years of High School: Correlates and Influences on Educational Outcomes, Aprile Benner and Sandra Graham.

The Generic/Non-Generic Distinction Influences How Children Interpret New Information About Social Others, Andrei Cimpian and Ellen M. Markman.

Two-Year Impacts of a Universal School-Based Social-Emotional and Literacy Intervention: An Experiment in Translational Developmental Research, Stephanie Jones, Joshua Brown, and J. Lawrence Aber.

Conditional Reasoning With False Premises Facilitates the Transition Between Familiar and Abstract Reasoning, Henry Markovits and Hugues Lortie Forgues.

When Easy Comes Hard: The Development of Adaptive Strategy Selection, Rui Mata, Bettina von Helversen, and Joerg Rieskmap.

Coherent Motion Sensitivity and Reading Development in the Transition From Pre-Reading to Reading Stage, Bart Boets, Maaike Vandermosten, Piers Cornelissen, Jan Wouters, and Pol Ghesquière.

Same-Ethnic Friendship Preferences Among German and Turkish Preadolescents Attending Ethnically Heterogeneous Schools, Philipp Jugert, Peter Noack, and Adam Rutland.

Holistic Face Processing in Newborns, 3-Month-Old Infants, and Adults: Evidence From the Composite Face Effect, Chiara Turati, Elisa Di Giorgio, Lara Bardi, and Francesca Simion.

Math-Gender Stereotypes in Elementary-School Children, Dario Cvencek, Andrew N. Meltzoff, and Anthony G. Greenwald.

Reporter Discrepancies Among Parents, Adolescents, and Peers: Adolescent Attachment and Informant Depressive Symptoms as Explanatory Factors, Katherine B. Ehrlich, Jude Cassidy, and Matthew J. Dykas.

Urban and Rural Chinese Adolescents' Judgments and Reasoning About Personal and Group Jurisdiction, Charles Helwig, Shaogang Yang, Dingliang Tan, Chunqiong Liu, and Tiffany Shao.

Childhood Trauma and Psychiatric Disorders as Correlates of School Dropout in a National Sample of Young Adults, Michelle V. Porche, Lisa R. Fortuna, Julia Lin, and Margarita Alegria.

The Role of Peer Relationships in the Development of Early School-Age Externalizing Problems, Cristina Sturaro, Pol A. C. van Lier, Pim Cuijpers, and Hans M. Koot.

Relationship Between Language Experiences in Preschool Classrooms and Children's Kindergarten and Fourth Grade Language and Reading Abilities, David K. Dickinson and Michelle V. Porche.

Intergenerational Transmission of Adaptive Functioning: A Test of the Interactionist Model of SES and Human Development, Thomas Schofield, Monica Martin, Katherine Conger, Brent Donnellan, Tricia Neppl, and Rand Conger.

Mentoring in Schools: An Impact Study of Big Brothers Big Sisters School-Based Mentoring, Carla Herrera, Jean Baldwin Grossman, Tina J. Kauh, and Jennifer McMaken.

Remission of Depression in Parents: Links to Healthy Functioning in Their Children, Judy Garber, Jeffrey A. Ciesla, Elizabeth McCauley, Guy Diamond, and Kelly A. Schloredt.

Double Jeopardy: Poorer Social-Emotional Outcomes for Children in the NICHD SECCYD Experiencing Home and Child Care Environments That Confer Risk, Sarah Watamura, Deborah Phillips, Taryn Morrissey, Kathleen McCartney, and Kristen Bub.

Imagining a Way Out of the Gravity Bias: Preschoolers Can Visualize the Solution to a Spatial Problem, Amy Joh, Vikram Jaswal, and Rachel Keen.

Sequential Progressions in a Theory of Mind Scale: Longitudinal Perspectives, Henry Wellman, Fuxi Fang, and Candida Peterson.

Can Maltreated Children Inhibit True and False Memories for Emotional Information?, Mark Howe, Sheree Toth, and Dante Cicchetti.

Parents' Involvement in Children's Learning in the United States and China: Implications for Children's Academic and Emotional Adjustment, Cecilia Cheung and Eva Pomerantz.

Four Children and One Toy: Chinese and Canadian Children Faced With Potential Conflict Over a Limited Resource, Doran French, Xinin Chen, Janet Chung, Miao Li, Dan Li, Huichang Chen, and Li Wang.

Influence of Eye Gaze on Spoken Word Processing: An ERP Study With Infants, Eugenio Parise, Andrea Handl, Letizia Palumbo, and Angela Friederici.

Infant and Maternal Sensitivity to Interpersonal Timing, Anne Henning and Tricia Striano.

Emotion Regulation Profiles, Temperament, and Adjustment Problems in Pre-adolescents, Maureen Zalewski, Liliana J. Lengua, Anna C. Wilson, Anika Trancik, and Alissa Bazinet.

Developmental Pathways to Integrated Social Skills: The Roles of Parenting and Early Intervention in Raising Healthy Children, Catherine Ayoub, Claire Vallotton, and Ann Mastergeorge.

Consequences of ''Minimal'' Group Affiliations in Children, Yarrow Dunham, Andrew Baron, and Susan Carey.

Revisiting the Impact of Part-Time Work on Adolescent Adjustment: Distinguishing Between Selection, Kathryn C. Monahan, Joanna Lee, and Laurence Steinberg.

Parents as Moderators of the Impact of School Norms and Peer Influences on Aggression in Middle School Students, Albert Farrell, David B. Henry, Sally Mays, and Michael E. Schoeny.

The ABC's of Family Mealtimes: Observational Lessons for Promoting Healthy Outcomes for Children With Persistent Asthma, Barbara Fiese, Marcia A. Winter, and Joanna Corra Botti.

Language Development in Internationally Adopted Children: A Special Case of Early Second Language Learning, Karine Gauthier and Fred Genesee.

Third-Party Social Interaction and Word Learning From Video, Kate O'Doherty, Georgene L. Troseth, Priya Shimpi, Elizabeth Goldenberg, Nameera Akhtar, and Megan M. Saylor.

Computer-Assisted Remedial Reading Intervention for School Beginners at Risk for Reading Disability, Nina Saine, Marja-Kristiina Lerkkanen, Timo Ahonen, Asko Tolvanen, and Heikki Lyytinen.

Desire for Increased Autonomy and Adolescents' Perceptions of Peer Autonomy: ''Everyone Else Can; Why Can't I?'', Christopher Daddis.

Almost Thinking Counterfactually: Children's Understanding of Close Counterfactuals, Sarah Beck and Carlie Guthrie.

CSRP's Impact on Low-Income Preschoolers' Pre-Academic Skills: Self-Regulation as a Mediating Mechanism, C. Cybele Raver, Stephanie M. Jones, Christine Li-Grining, Fuhua Zhai, Kristen Bub, and Emily Pressler.

Does God Make It Real? Children's Belief in Religious Stories From the Judeo-Christian Tradition, Victoria Cox Vaden and Jacqueline D. Woolley.

Changes in Early Adolescents' Sense of Responsibility to Their Parents in the United States and China: Implications for Their Academic Functioning, Eva Pomerantz, Lili Qin, Qian Wang, and Huichang Chen.

Two- to Eight-Month-Old Infants' Perception of Dynamic Auditory-Visual Spatial Co-Location, Gavin Bremner, Alan Slater, Scott Johnson, Uschi Mason, Jo Spring, and Maggie Bremner.

Longitudinal Associations Between Marital Instability and Child Sleep Problems Across Infancy and Toddlerhood in Adoptive Families, Anne Mannering, Gordon Harold, Leslie Leve, Katherine Shelton, Daniel Shaw, Rand Conger, Jenae Neiderhiser, Laura Scaramella, and David Reiss.

Promoting Effective Parenting Practices and Preventing Child Behavior Problems in School, Laurie Brotman, Esther Calzada, Keng-Yen Huang, Sharon Kingston, Spring Dawson-McClure, Dimitra Kamboukos, Amanda Rosenfelt, Ami Schwab, and Eva Petkova.

Age 26 Cost–Benefit Analysis of the Child–Parent Center Early Education Program, Arthur Reynolds, Judy Temple, Barry White, Suh-Ruu Ou, and Dylan Robertson.

Infantile Amnesia Across the Years: A 2-Year Follow-Up of Children's Earliest Memories, Carole Peterson, Kelly L. Warren, and Megan M. Short.

Hemoglobin, Growth, and Attention of Infants in Southern Ethiopia, Nicki Aubuchon-Endsley, Stephanie L. Grant, Getenesh Berhanu, David G. Thomas, Sarah Schrader, Devon Eldridge, Tay S. Kennedy, and Michael Hambidge.

Transition From Crawling to Walking and Infants' Actions With Objects and People, Lana Karasik, Catherine Tamis-LeMonda, and Karen Adolph.

The Genetic and Environmental Covariation Among Psychopathic Personality Traits and Reactive and Proactive Aggression in Childhood, Serena Bezdjian, Catherine Tuvblad, Adrian Raine, and Laura A. Baker.

Structure Mapping and Relational Language Support Children's Learning of Relational Categories, Dedre Gentner, Florencia K. Anggoro, and Raquel S. Klibanoff.

Narrative Elaboration and Participation: Two Dimensions of Maternal Elicitation Style, Gigliana Melzi, Adina R. Schick, and Joy L. Kennedy.

Does Felt Gender Compatibility Mediate Influences of Self-Perceived Gender Nonconformity on Early Adolescents' Psychosocial Well-Being?, Meenakshi Menon.

Theory of Mind and Social Interest in Zero Acquaintance Play Situations, Chris Moore, Sandra Bosacki, and Shannon Macgillivray.

Media as Social Partners: The Social Nature of Young Children's Learning From Screen Media, Rebekah Richert, Michael B. Robb, and Erin I. Smith.

Protecting Children From the Consequences of Divorce: A Longitudinal Study of the Effects of Parenting on Children's Coping Processes, Clorinda Velez, Sharlene Wolchik, Jenn-Yun Tein, and Irwin Sandler.

Preschoolers' Quarantining of Fantasy Stories, Rebekah Richert and Erin I. Smith.

Effect of Foster Care on Young Children's Language Learning, Jennifer Windsor, Joann Benigno, Christine Wing, Patrick Carroll, Sebastian Koga, Charles Nelson, Nathan Fox, and Charles Zeanah.

Why Don't Smart Teens Have Sex? A Behavioral Genetic Approach, Kathryn Paige Harden and Jane Mendle.

Preschoolers' Use of Morphosyntactic Cues to Identify Generic Sentences: Indefinite Singular Noun Phrases, Tense, and Aspect, Andrei Cimpian, Trent J. Meltzer, and Ellen M. Markman.

Impaired Acuity of the Approximate Number System Underlies Mathematical Learning Disability, Michele Mazzocco, Lisa Feigenson, and Justin Halberda.

Imitation in Infancy: Rational or Motor Resonance?, Markus Paulus, Sabine Hunnius, Marlies Vissers, and Harold Bekkering.

Effects of Non-Maternal Care in the First Three Years on Children's Academic Skills and Behavioral Functioning in Childhood and Early Adolescence, Sara Jaffee, Carol Van Hulle, and Joseph Rodgers.

Shyness-Sensitivity and Unsociability in Rural Chinese Children: Relations with Social, School, and Psychological Adjustment, Xinyin Chen and Li Wang.

Age Differences in Strategic Planning as Indexed by the Tower of London, Dustin Albert and Laurence Steinberg.

Young Children's Learning and Transfer of Biological Information From Picture Books to Real Animals, Patricia Ganea, Lili Ma, and Judy DeLoache.

Characterizing Children's Expectations About Expertise and Incompetence: Halo or Pitchfork Effects?, Melissa Koenig and Vikram K. Jaswal.

Wherein Lies Children's Intergroup Bias? Egocentrism, Social Understanding, and Social Projection, Dominic Abrams.

Can Children With Autism Spectrum Disorders "Hear" a Speaking Face?, Julia Irwin, Lawrence Brancazio, Lauren Tornatore, and D.H. Whalen.

The Home Learning Environment Across the First Five Years: Associations With Children's Vocabulary and Emergent Literacy Skills at Pre-Kindergarten, Eileen T. Rodriguez and Catherine S. Tamis-LeMonda.

A Longitudinal Examination of African American Adolescents' Attributions About Achievement Outcomes, Akilah Swinton, Beth Kurtz-Costes, Stephanie Rowley, and Ndidi Okeke.

Ethnic Stigma, Academic Anxiety, and Intrinsic Motivation in Middle Childhood, Cari Gillen-O'Neel, Diane N. Ruble, and Andrew J. Fuligni.

Examining the Black-White Achievement Gap Among Low-Income Children: Using the NICHD Study of Early Child Care and Youth Development, Margaret Burchinal, Kathleen McCartney, Laurence Steinberg, Robert Crosnoe, Sarah L. Friedman, Vonnie McLoyd, and Robert Pianta.

A Longitudinal Study of Religious Identity and Participation During Adolescence, Anna Lopez, Virginia Huynh, and Andrew Fuligni.

Benefits of Practicing 4 = 2 + 2: Nontraditional Problem Formats Facilitate Children's Understanding of Mathematical Equivalence, Nicole M. McNeil, Emily R. Fyfe, Lori A. Petersen, April E. Dunwiddie, and Heather Brletic-Shipley.

Reciprocal Associations Between Family and Peer Conflict in Adolescents' Daily Lives, Grace Chung, Lisa Flook, and Andrew Fuligni.

The Development of Distrust, Kimberly Vanderbilt, David Liu, and Gail Heyman.

Developing Relationships, Being Cool, and Not Looking Like a Loser: Social Goal Orientation Predicts Children's Responses to Peer Aggression, Karen D. Rudolph, Jamie L. Abaied, Megan Flynn, Niwako Sugimura, and Anna Monica Agoston.

Nonlinear Growth Curves in Developmental Research, Kevin Grimm, Nilam Ram, and Fumiaki Hamagami.

Developmental Continuity in Theory of Mind: Speed and Accuracy of Belief-Desire Reasoning in Children and Adults, Ian Apperly, Frances Warren, Benjamin Andrews, Jay Grant, and Sophie Todd.

Children's Judgments of Emotion From Conflicting Cues in Speech: Why 6-Year-Olds Are so Inflexible, Matthew Waxer and J. Morton.

Social-Emotional Effects of Early Childhood Education Programs in Tulsa, William Gormley Jr., Deborah A. Phillips, Katie Newmark, Kate Perper, and Shirley Adelstein.

The Development of Uncertainty Monitoring in Early Childhood, Kristen E. Lyons and Simona Ghetti.

Critical Consciousness Development and Political Participation Among Marginalized Youth, Matthew Diemer and Cheng-Hsien Li.

The Moderating Capacity of Racial Identity Between Perceived Discrimination and Psychological Well-Being Over Time Among African American Youth, Eleanor Seaton, Enrique Neblett, Rachel D. Upton, Wizdom Powell Hammond, and Robert Sellers.

Antecedents and Outcomes of Joint Trajectories of Mother–Son Conflict and Warmth During Middle Childhood and Adolescence, Christopher Trentacosta, Michael Criss, Daniel Shaw, Eric Lacourse, Luke Hyde, and Thomas Dishion.

Parenting and Infant Difficulty: Testing a Mutual Exacerbation Hypothesis to Predict Early Onset Conduct Problems, Michael Lorber and Byron Egeland.

Vision for Action in Toddlers: The Posting Task, Sandra Y. Street, Karin H. James, Susan S. Jones, and Linda B. Smith.

The Gap Between Spanish-Speakers' Word Reading and Word Knowledge: A Longitudinal Study, Jeannette Mancilla-Martinez and Nonie K. Lesaux.

African American and European American Children in Diverse Elementary Classrooms: Social Integration, Social Status, and Social Behavior, Travis Wilson and Philip C. Rodkin.

Characterizing and Comparing the Friendships of Anxious-Solitary and Unsociable Preadolescents, Gary Ladd, Becky Kochenderfer-Ladd, Natalie D. Eggum, Karen Kochel, and Erin McConnell.

The Effect of Narrative Cues on Infants' Imitation from Television and Picture Books, Gabrielle Simcock, Kara Garrity, and Rachel Barr.

Social Groups and Children's Intergroup Attitudes: Can School Norms Moderate the Effects of Social Group Norms?, Drew Nesdale and Michael J. Lawson.

Differential Susceptibility to Adolescent Externalizing Trajectories: Examining the Interplay Between CHRM2 and Peer Group Antisocial Behavior, Shawn Latendresse, John Bates, Jackson Goodnight, Kenneth Dodge, Jennifer Lansford, Gregory Pettit, John Budde, Alison Goate, and Danielle Dick.

Newborn Irritability Moderates the Association Between Infant Attachment Security and Toddler Exploration and Sociability, Brandi Stupica, Laura J. Sherman, and Jude Cassidy.

Child Development, November/December 2010, Volume 81, Number 6, Pages 1911–1916

Editorial Acknowledgments

Over the past year, many developmental scientists, in addition to our Consulting Editors, have participated in the peer review process at *Child Development*. These individual efforts are, invariably by their very nature, anonymous. But at the end of the calendar year, we are delighted to be able to acknowledge these experts' important contributions. It is not an exaggeration to state that their input is as much embodied in the pages of *CD* as are those of our authors. I also want to take this opportunity to acknowledge the immeasurable contributions of Mary Dozier, Nancy G. Guerra, D. Geoffrey Hall, and Betsy Hoza, all of whom completed their terms as Associate Editor during this calendar year and have elected to step down from this post. The field has benefited enormously from their collective wisdom. And on a personal note, it has been a great privilege for me to work with these individuals. I am also honored and delighted to announce that Karen Bierman, Gil Diesendruck, Bonnie J. Leadbeater, and Glenn I. Roisman have accepted appointments as Associate Editors of the journal. I welcome their contributions to *Child Development* and to the field.

—*Jeffrey J. Lockman*

UNIVERSITY OF ALABAMA AT BIRMINGHAM: The UAB Department of Psychology is seeking nominations and applications for a new **Endowed Chair in Developmental Psychology**. This is a tenured position at the Associate or Full Professor level. The candidate should be a psychologist with expertise in child or adolescent research and a strong record of scholarship and extramural funding in lifespan development, child clinical or pediatric psychology. The successful candidate for this position will be expected to lead an active and externally funded program of research, mentor graduate and undergraduate students, and will have the opportunity to teach in his/her area of expertise.

The Psychology Department is a vibrant and well regarded department on campus and supports three doctoral programs (Lifespan Developmental, Medical Clinical, and Behavioral Neuroscience). The Department has a long history of obtaining extramural research funding and has excellent research facilities. In addition, as part of the University's emphasis on multidisciplinary centers, the Psychology Department encourages/supports collaboration with various departments and centers within the university including the Civitan International Research Center, the Civitan/Sparks Clinics, The Children's Health System, The Comprehensive Cancer Center, the Center for Neuroscience, The McKnight Brain Institute, The Center for Community Health, The Center for Translational Science, The Center for Aging, and the School of Medicine. Individuals interested in participating, promoting, and advancing a collaborative and multidisciplinary environment at UAB and in the community are encouraged to apply.

The Psychology Department enjoys the benefits of UAB's standing as a national center for biomedical health research and education. Metro Birmingham (population 1.2 million) is an ethnically diverse and cosmopolitan setting with a rich array of cultural institutions and a high quality of life.

Applicants should send a letter of interest, CV, representative reprints, and the names of three professional references to: **Dr. Fred Biasini, Chair, Developmental Psychology Search Committee, Department of Psychology, University of Alabama at Birmingham, 1530 3rd Avenue South, Birmingham, AL 35294-1170. For questions about the positions, please contact Dr. Biasini (fbiasini@uab.edu) or Dr. Karlene Ball (kball@uab.edu), University Professor and Chair, Department of Psychology.** Screening of applications will begin in Fall 2010 and continue until the position is filled. Starting date is negotiable.

UAB is dedicated to broadening the diversity of its faculty, staff, and students. We take pride in our exceptionally diverse and multicultural student body. UAB is an Equal Opportunity/Affirmative Action employer. Women and minority candidates are encouraged to apply.

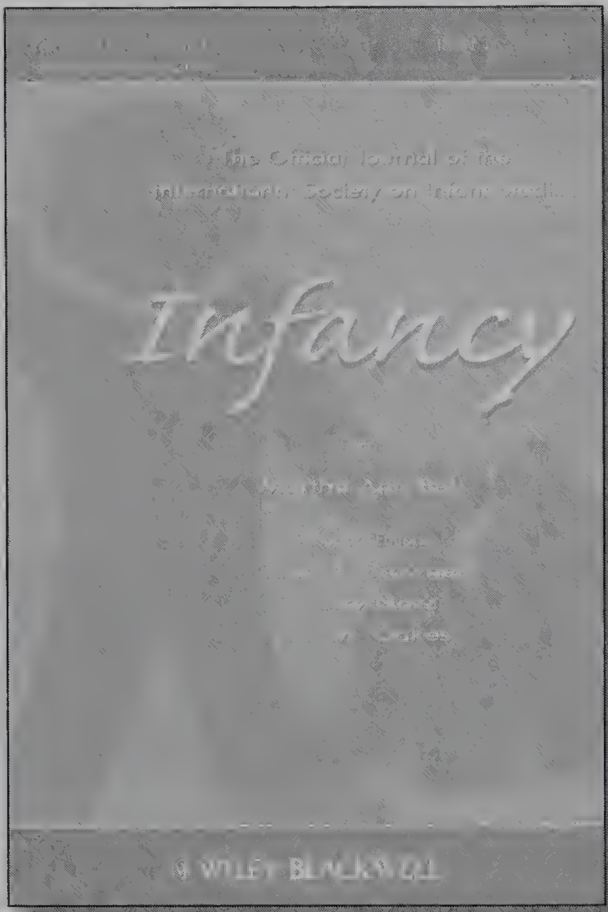
WILEY-
BLACKWELL
The Place to Publish

Wiley-Blackwell's industry-leading books and journals publishing program, advanced online delivery platform, high-quality and cost-effective production values, extensive global marketing and sales reach, and state-of-the-art services for societies, editors and authors make Wiley-Blackwell the place to publish across all disciplines.



Infancy

Edited by
MARTHA ANN BELL

Published on behalf of the International Society on Infant Studies

Infancy, the official journal of the International Society on Infant Studies, emphasizes the highest quality original research on normal and aberrant infant development during the first two years. Both human and animal research are included. In addition to regular length research articles and brief reports (3000-word maximum), the journal includes solicited target articles along with a series of commentaries; debates, in which different theoretical positions are presented along with a series of commentaries; and thematic collections, a group of three to five reports or summaries of research on the same issue, conducted independently at different laboratories, with invited commentaries.

c. Total Paid Distribution *(Sum of 15b (1), (2),(3), and (4))*			4122	4730
d. Free or Nominal Rate Distribution *(By Mail and Outside the Mail)*	(1)	Free or Nominal Rate Outside-County Copies Iincluded on PS Form 3541	92	89
	(2)	Free or Nominal Rate In-County Copies Included on PS Form 3541	0	0
	(3)	Free or Nominal Rate Copies Mailed at Other Classes Through the USPS (e.g. First-Class Mail)	0	0
	(4)	Free or Nominal Rate Distribution Outside the Mail *(Carriers or other means)*	0	0
e. Total Free or Nominal Rate Distribution *(Sum of 15d (1), (2), (3) and (4)*			92	89
f. Total Distribution *(Sum of 15c and 15e)* ▶			4214	4819
g. Copies not Distributed *(See Instructions to Publishers #4 (page #3))* ▶			1890	551
h. Total *(Sum of 15f and g)* ▶			6104	5370
i. Percent Paid *(15c divided by 15f times 100)* ▶			97.82	98.15

16. Publication of Statement of Ownership
☑ If the publication is a general publication, publication of this statement is required. Will be printed in the December 2010 issue of this publication.
☐ Publication not required

17. Signature and Title of Editor, Publisher, Business Manager, or Owner: Elizabeth Konkle, Associate Financial Manager

Date: 10/1/10

I certify that all information furnished on this form is true and complete. I understand that anyone who furnishes false or misleading information on this form or who omits material or information requested on the form may be subject to criminal sanctions (including fines and imprisonment) and/or civil sanctions (including civil penalties).

Notice to Contributors

Child Development publishes empirical, theoretical, review, applied, and policy articles reporting research on child development. Published by the interdisciplinary Society for Research in Child Development (SRCD), the journal welcomes relevant submissions from all disciplines. Further information is available at http://www.srcd.org/cd.html.

Types of Articles

Child Development considers manuscripts in formats described below. Inquiries concerning alternative formats should be addressed to the Editor prior to submission. All submissions are expected to be no more than 40 manuscript pages, including tables, references, and figures (but excluding appendices). Authors should provide a justification if the submission is substantially longer. Unless the editor finds that justification compelling, the submission will be returned to the author for shortening prior to editorial review.

Empirical articles comprise the major portion of the journal. To be accepted, empirical articles must be judged as being high in scientific quality, contributing to the empirical base of child development, and having important theoretical, practical, or interdisciplinary implications. Reports of multiple studies, methods, or settings are encouraged, but single-study reports are also considered. Empirical articles will thus vary considerably in length, but should be no longer than 40 manuscript pages; text and graphics should be as concise as material permits. All modes of empirical research are welcome.

Empirical reports are reserved for short cutting-edge empirical papers that are no longer than 4,000 words in length (including text, tables, footnotes, appendices), which advance research and knowledge in an area through noteworthy findings and/or new methods. For manuscripts that require longer descriptions of methods and results, authors should use the Empirical article format.

Reviews focus on past empirical and/or on conceptual and theoretical work. They are expected to synthesize or evaluate a topic or issue relevant to child development, should appeal to a broad audience, and may be followed by a small number of solicited commentaries.

Essays describe original concepts, methods, trends, applications, and theories; these may also be accompanied by solicited commentaries.

Child Development and … are articles that provide readers with tutorials about some new concept or academic specialty pertinent to research in child development. These papers should review the major definitions, methods, and findings of the concept or specialty and discuss past or potential links to child development.

From another perspective is a format in which papers on a focal topic, written by different authors, are published simultaneously. Papers represent diverse perspectives (e.g., authors whose work represents different populations; different disciplines; different theories, methods, or analytic tools). In some cases, calls for submissions on particular topics will be disseminated through SRCD (via e-mail or SRCD publications), and submissions will undergo normal editorial review. In some cases, a submitted manuscript (e.g., an empirical article) may be selected as a lead article for this format, with invited commentaries providing additional perspectives. The editors also welcome suggestions from readers for topics for this format.

Manuscript Submission

Child Development invites for consideration manuscripts that are neither identical to nor substantially similar to work published or under review elsewhere. In the submission cover letter, please provide details about other published or submitted papers having substantial overlap (including data sets) with the new CD submission to enable editors to judge whether the new submission is sufficiently distinct from other work to warrant consideration. Please note if the paper is posted on a website, see http://www. srcd.org/web posting. html. Editors retain the right to reject manuscripts that do not meet established ethical standards for research or dissemination.

Manuscripts should be submitted electronically to the Child Development Online Submission Site at www.srcd.org /CDsubmit/ as a Word or WordPerfect file. Please also submit a cover letter that contains the name(s) of the author(s) and affiliation(s), and the street address, telephone, fax, and electronic mail address of the corresponding author. A corresponding author's submission to *Child Development* implies that all coauthors have agreed to the content and form of the manuscript and that the ethical standards of SRCD have been followed (see the *Child Development* website or pp. 283–284 of the 2000 SRCD Directory). Any financial interest or conflict of interest must be explained to the Editor in the cover letter. The corresponding author is responsible for informing all coauthors, in a timely manner, of manuscript submission, editorial decisions, reviews, and revisions. Please note that if your submission (or its revision) is accepted for publication, each author must submit a signed Exclusive License Form (http://www.srcd.org/Documents/Publications/CD/cdcopyright.pdf) before the manuscript can enter production. Planning ahead to meet this requirement is especially important for manuscripts with multiple authors.

The manuscript file should be formatted with double-spaced, 12-point type, and should include a single paragraph abstract of 100–120 words. Please follow all guidelines on format, style, and ethics provided in the Publication Manual (6th ed.) of the American Psychological Association. Figures included with initial submissions will not be returned. Therefore, please submit only electronic files or copies of figures. If color artwork is submitted, and the authors believe color art is necessary to the presentation of their work, the submissions letter should indicate that one or more authors or their institutions are prepared to pay the substantial costs associated with color art reproduction. Authors should keep a copy of all correspondence, files, and figures to guard against loss.

Manuscript Review

If you have any questions about your submission, please inquire at cdev@srcd.org or call (734) 926-0615. Each manuscript is handled by the Editor or an Associate Editor who consults with one or more Consulting Editors and/or ad hoc reviewers who have relevant expertise. To ensure blind review, cover sheets are removed before review; authors should avoid including any other information about identity or affiliation in submissions. Copies of the submission and associated correspondence are retained in the SRCD archives. For accepted manuscripts, authors are required to prepare a 300–500 layperson's summary for public dissemination purposes. Details are provided to authors as part of final processing.

There is no charge for publication in *Child Development* unless tabular or graphic materials exceed 10% of the total number of pages. Charges are also levied for changes in proofs other than correction of printer's errors. Any inquiries relating to charges or business matters (including reprint orders) should be addressed to Wiley-Blackwell, *Child Development*, Production Coordinator, 350 Main Street, Malden, MA 02148, (781) 388-8200.

Inquiries and suggestions regarding editorial policy may be addressed to: Dr. Jeffrey J. Lockman, Editor, *Child Development*, Department of Psychology, Tulane University, 2007 Percival Stern Hall, New Orleans, LA 70118-5698, lockman@tulane.edu. *Please do not send electronic or paper manuscripts to the above address.* Doing so will delay the processing of your manuscript.

Note to NIH Grantees

Pursuant to NIH mandate, Society through Wiley-Blackwell will post the accepted version of Contributions authored by NIH grantholders to PubMed Central upon acceptance. This accepted version will be made publicly available 12 months after publication. For further information, see www.wiley.com/go/nihmandate.

MONOGRAPHS OF THE SOCIETY FOR RESEARCH IN CHILD DEVELOPMENT

Recent

FIRST-YEAR MATERNAL EMPLOYMENT AND CHILD DEVELOPMENT IN THE FIRST 7 YEARS

- *Jeanne Brooks-Gunn, Wen-Jui Han, and Jane Waldfogel* (Serial No. 296, 2010).

DEPRIVATION-SPECIFIC PSYCHOLOGICAL PATTERNS: EFFECTS OF INSTITUTIONAL DEPRIVATION

- *Michael Rutter, Edmund J. Sonuga-Barke, Celia Beckett, Jennifer Castle, Jana Kreppner, Robert Kumsta, Wolff Schlotz, Suzanne Stevens, and Christopher A. Bell* (Serial No. 295, 2010).

A DYNAMIC CASCADE MODEL OF THE DEVELOPMENT OF SUBSTANCE-USE ONSET

- *Kenneth A. Dodge, Patrick S. Malone, Jennifer E. Lansford, Shari Miller, Gregory S. Pettit, and John E. Bates* (Serial No. 294, 2009).

FLEXIBILITY IN EARLY VERB USE: EVIDENCE FROM A MULTIPLE-*N* DIARY STUDY

- *Letitia R. Naigles, Erika Hoff, and Donna Vear* (Serial No. 293, 2009).

MARITAL CONFLICT AND CHILDREN'S EXTERNALIZING BEHAVIOR: INTERACTIONS BETWEEN PARASYMPATHETIC AND SYMPATHETIC NERVOUS SYSTEM ACTIVITY

- *Mona El-Sheikh et al.* (Serial No. 292, 2009).

THE EFFECTS OF EARLY SOCIAL-EMOTIONAL AND RELATIONSHIP EXPERIENCE ON THE DEVELOPMENT OF YOUNG ORPHANAGE CHILDREN

- *The St. Petersburg–USA Orphanage Research Team* (Serial No. 291, 2008).

UNDERSTANDING MOTHER-ADOLESCENT CONFLICT DISCUSSIONS: CONCURRENT AND ACROSS-TIME PREDICTION FROM YOUTHS' DISPOSITIONS AND PARENTING

- *Nancy Eisenberg et al.* (Serial No. 290, 2008).

DEVELOPING OBJECT CONCEPTS IN INFANCY: AN ASSOCIATIVE LEARNING PERSPECTIVE

- *David H. Rakison and Gary Lupyan* (Serial No. 289, 2008).

THE GENETIC AND ENVIRONMENTAL ORIGINS OF LEARNING ABILITIES AND DISABILITIES IN THE EARLY SCHOOL YEARS

- *Yulia Kovas, Claire M. A. Haworth, Philip S. Dale, and Robert Plomin* (Serial No. 288, 2007).

THE PRESERVATION OF TWO INFANT TEMPERAMENTS INTO ADOLESCENCE

- *Jerome Kagan, Nancy Snidman, Vali Kahn, and Sara Towsley* (Serial No. 287, 2007).

CHILDREN'S QUESTIONS: A MECHANISM FOR COGNITIVE DEVELOPMENT

- *Michelle M. Chouinard* (Serial No. 286, 2007).

BEST PRACTICES IN QUANTITATIVE METHODS FOR DEVELOPMENTALISTS

- *Kathleen McCartney, Margaret R. Burchinal, and Kristen L. Bub* (Serial No. 285, 2006).

FOUNDATIONS OF SELF-AWARENESS: AN EXPLORATION THROUGH AUTISM

- *R. Peter Hobson, Gayathri Chidambi, Anthony Lee, and Jessica Meyer* (Serial No. 284, 2006).

OUR CHILDREN TOO: A HISTORY OF THE BLACK CAUCUS
OF THE SOCIETY FOR RESEARCH IN CHILD DEVELOPMENT, 1973–1997

- *Diana T. Slaughter-Defoe, Aline M. Garrett, and Algea O. Harrison-Hale* (Serial No. 283, 2006).

PARENTAL SUPPORT, PSYCHOLOGICAL CONTROL, AND BEHAVIORAL CONTROL:
ASSESSING RELEVANCE ACROSS TIME, CULTURE, AND METHOD

- *Brian K. Barber, Heidi E. Stolz, and Joseph A. Olsen* (Serial No. 282, 2005).

BEING HURT AND HURTING OTHERS: CHILDREN'S NARRATIVE ACCOUNTS
AND MORAL JUDGMENTS OF THEIR OWN INTERPERSONAL CONFLICTS

- *Cecilia Wainryb, Beverly A. Brenl, and Sonia Matwin* (Serial No. 281, 2005).

CHILDHOOD SEXUAL ASSAULT VICTIMS: LONG-TERM OUTCOMES AFTER TESTIFYING IN CRIMINAL COURT

- *Jodi A. Quas, Gail S. Goodman, Simona Ghetti, Kristen Weede Alexander, Robin Edelstein, Allison D. Redlich, Ingrid M. Cordon, and David P. H. Jones* (Serial No. 280, 2005).

THE EMERGENCE OF SOCIAL COGNITION IN THREE YOUNG CHIMPANZEES

- *Michael Tomasello and Malinda Carpenter* (Serial No. 279, 2005).

TRAJECTORIES OF PHYSICAL AGGRESSION FROM TODDLERHOOD TO MIDDLE CHILDHOOD:
PREDICTORS, CORRELATES, AND OUTCOMES

- *NICHD Early Child Care Research Network* (Serial No. 278, 2004).

CONSTRAINTS ON CONCEPTUAL DEVELOPMENT: A CASE STUDY OF THE ACQUISITION OF
FOLKBIOLOGICAL AND FOLKSOCIOLOGICAL KNOWLEDGE IN MADAGASCAR

- *Rita Astuti, Gregg E. A. Solomon, and Susan Carey* (Serial No. 277, 2004).
